Long-established systems in the 12,000-volt delta class indicated the necessity of providing a delta voltage standard for this rating.

In the next higher voltage class considerable confusion existed in voltage ratings. For many years there had existed a standard rating of 13,800 volts to 115/230 volts. Later this was superseded by a rating of 13,200 volts to 120/240 volts. However, because of the difference in ratio, many users continued to specify the previous standard. If the previous standard were to be rerated on a 120-volt base, its rating would become 14,400 volts to 120/240 volts. This would match the top level of some systems but would be altogether too high for the systems actually operating at 13,200 volts. On the other hand, the usage hardly justified having two complete sets of ratings all the way through 500 kva. The final result was a compromise in which the two ratings were combined in sizes 3 to 100 kva, providing a voltage spread from 14,400 volts all the way down to 12,540 volts. In the ratings above 100 kva two lines were standardized: a 13,200-volt line with conventional voltage taps, and a 14,400-volt line with taps at 14,100, 13,800, 13,500, and 13,200 volts. Although not a perfect answer, this solution has proved an economical and generally acceptable answer to a rather difficult problem.

Other primary voltages in actual service were considered and left out of the standards because their comparatively limited usage did not justify their addition to a list of distribution transformer ratings already seriously overburdened by a multiplicity of voltages, kilovolt-ampere ratings, and tap combinations. Among the voltages omitted for this reason were 2,080/4,160, 2,170, 2,200/-3,810Y, 3,415, 5,500, 6,900, and 16,500 volts.

The selection of the secondary voltage ratings was considerably easier than that of the primary. The use of 120/240 volts for series, multiple, or 3-wire was widespread in the small and intermediate ratings and of 240/120 volts, 3-wire in the larger sizes. The former combination therefore was standardized through 167 kva, and the latter in ratings 250-500 kva. A 600-volt secondary rating also was necessary for those sections of the country where 550-volt industrial applications were widespread.

In the class between, covering 240-volt and 480-volt applications in a single transformer, the main question was which sizes should be rated 240/480 volts, making them suitable for 240 volts, 480 volts, or 480/240 volts 3-wire. The 3-wire connection was needed by some users in some sizes. Others wanted this connection available for grounding the middle of one leg of the low-voltage delta. On the other hand, this type of secondary requires interlacing of the two halves of the secondary winding which would add materially to the cost in the larger kilovolt-ampere ratings. The alternative rating would be 240 × 480 volts which provides 240 volts or 480 volts but not the 3-wire connection. Here again the advice of a large majority of users indicated a compromise in which sizes up to and including 100 kva were rated 240/480 volts and sizes 167-500 kva were rated 240 × 480 volts.

The final aspect of the voltage rating, and one that was the hardest to determine, was the matter of taps. The problems here were: first, on which standard transformers should taps be omitted altogether; and second, where should the taps be located when included. A range of 10 per cent and a total of four taps were quickly conceded to be adequate except in the 13,200/14,400-volt class already discussed.

It will be noted that in the 2,400-volt, 4,800-volt, and 2,400 × 4,800-volt classes there are lines of standard transformers without taps, the limit being 50 kva in the 2,400-volt and 4,800-volt class and 167 kva in the 2,400 × 4,800-volt class. A very substantial usage of these nontapped transformers has prevailed for many years. Furthermore, such units were obviously simpler and less expensive to build than the tapped units. However, in this voltage and kilovolt-ampere class there also existed the need for tapped units, some users requiring the taps to match older 9-to-1 systems, others to adjust the voltage to that best suited to the various supply requirements on their particular systems. This was recognized in the 2,400-volt and 4,800-volt units by making an alternate standard line with taps. In the case of the 4,160-volt units, the demand was not sufficient to justify both tapped and nontapped units; the tapped units, representing a more universal usage were, therefore, standardized. In the case of the 2,400 × 4,800 transformers the difficulty of making such

Table VII. Distribution Transformers*

Preferred Voltage Ratings

The Joint Committee on Preferred Voltage Ratings concurs with and reproduces herewith the recommendations contained in the Fourth Report[4] of the EEI-NEMA Joint Committee on Standards for Distribution Transformers for voltage ratings of transformers having high-voltage ratings 14,400 volts and below, with low-voltage ratings 600 volts and below; and in sizes up to 500 kva, inclusive.

The low-voltage ratings of these transformers are all on a 120-volt base. In general, where high-voltage taps are provided on units having low-voltage ratings for lighting service (120/240, 240/120, or 208Y/120), the taps are located below rated voltage; and on units having low-voltage ratings for motor service (240, 480, 240/480, 240 × 480, and 600), the taps are located equally above and below rated voltage. Exception is made in the case of 7,620 volts where the taps on units with lighting secondaries are above and below to meet the joint needs of 7,620- and 8,000-volt systems and on 14,400-volt units where definite voltages are selected as shown to combine several classes in ratings 100 kva and smaller and to provide paralleling ratios on larger kilovolt-ampere ratings in the same voltage class. Also, for certain industrial applications involving use of 3-phase units, indoors at load centers or power centers, the taps on transformers with 208Y/120 low-voltage rating are located equally above and below rated voltage.

For voltage ratings of distribution transformers (500 kilovolt amperes and smaller) with low-voltage rating 2,400 volts and above, and also for those with high voltage ratings above 14,400 volts, the preferred voltages are the same as those shown for power transformer in Table VI.

Table VIIA. Single-Phase Distribution Transformers

Transformers with low voltage rated 120/240 volts or rated 240/480 volts are suitable for series or parallel or 3-wire operation at full kilovolt-ampere rating. Transformers, with low voltage rated 240 × 480 are suitable for operation at 240 volts or 480 volts but not suitable for operation at both voltages simultaneously.

Transformers with low voltage rated 240/120 volts are suitable for 3-wire operation at full kilovolt-ampere rating but are not suitable for multiple operation at 120 volts.

High-Voltage Rating	High-Voltage Taps: Above	High-Voltage Taps: Below	Minimum and Maximum Kva Ratings for Low-Voltage Ratings of: 120/240	240/120	240/480	240×480	600

* Reproduced from Table 10, reference 1 of this paper. ** Electrical performance characteristics shall be at 14,400 volts.

† Transformers in this class, 100 kva and smaller, are designed to cover in one rating the general voltage range 13,000–15,000 volts. The lowest voltage shall be reduced kilovolt-ampere rating. All other voltages shall be at rated kilovolt amperes. †† One high-voltage bushing only.

Table VIIB. Three-Phase Distribution Transformers

Transformers with low voltage rated 208Y/120 volts are suitable for 208Y/120-volt 4-wire operation, but not for 120-volt 3-wire delta operation, and on such transformers for certain applications indoors, at load centers or power centers, the standard high-voltage taps should be 2–2½-per cent full kilovolt-ampere taps below and 2–2½-per cent full kilovolt-ampere taps above rated voltage. Transformers with low voltage rated 240 × 480 volts are suitable for operation at 240 volts or 480 volts but not suitable for operation at both voltages simultaneously.

For certain industrial applications involving the use of 75–500 kva, 3-phase, units used indoors at load centers, low-voltage ratings of 240 volts delta or 480 volts delta or 480Y/277 volts or 600Y/346 volts should be considered as an alternate preferred voltage rating.

To provide for industrial distribution at a level suitable for 6,600-volt motors and control equipment, a high-voltage rating of 6,900 volts used with low-voltage ratings in multiples of 120 volts should be considered an alternate preferred voltage rating for 3-phase transformers. Taps on such units should be the same percentage taps and located similarly to those used for the 7,200-volt high-voltage ratings having the same low-voltage ratings.

High-Voltage Rating	High-Voltage Taps: Above	High-Voltage Taps: Below	Minimum and Maximum Kva Ratings for Low-Voltage Ratings of: 208Y/120	240* Delta or 480 Delta	240×480 Delta*	600 Delta

units suitable for both series-parallel connection and taps led to the adoption of the simpler units without taps as standard.

In the 7,200-volt and 7,620-volt class, the Second Report[3] of the EEI-NEMA Joint Committee established the smaller kilovolt-ampere ratings as standard without taps. However, this did not prove generally acceptable and a resurvey among users of these voltage classes indicated a preponderant desire for taps even in these smaller ratings. A minority of companies felt that transformers without taps should continue as standard. Therefore, to provide for further observation and study, single-bushing transformers in the 3-kva and 5-kva ratings, 7,200-volt and 7,620-volt ratings, were standardized both with and without taps. In this connection the following comments quoted from the Fourth Report[4] of the Joint EEI-NEMA Committee on Standards for Distribution Transformers are pertinent:

"Although some system conditions make taps a necessity for immediate needs, users are urged to study system voltage levels and auxiliary means of regulating voltage with the objective of obtaining the maximum economies from the use of standard non-tapped transformers. Tapped transformers will be available for those situations where omission of taps appears impractical, but it is urged that the nontapped standard units be used wherever possible."

On the remaining ratings, except as previously noted, taps were standardized throughout in accordance with indicated usage, both as to magnitude and application needs.

The position of the taps on those units where taps are standard is also very important. For units having lighting secondaries, that is, 120/240 volts, there was unanimous agreement that below-normal taps should be provided. Except for one case in the 7,620-volt class, which will be mentioned later, the general standard for such units, therefore, became four $2^1/_2$-per cent taps below rated voltage on the high side.

In considering transformers used to supply motors and control, involving secondaries of 240/480 volts, 240 × 480 volts, or 600 volts, consultation with the AIEE Subcommittee on Industrial Power Applications brought out the need for taps above rated voltage, as well as taps below, in order to deliver a lower secondary voltage which would more nearly match the normal motor and control voltage ratings of 220, 440, and 550 volts. As a result, for such transformers two $2^1/_2$-per cent taps above and two $2^1/_2$-per cent taps below rated voltage were provided. In the earlier Joint Committee Reports these taps were applied only to voltage levels having ratings of 5,000 volts and below. It quickly became evident, however, that the same considerations existed at levels above 5,000 volts so that the practice was extended to higher voltages as well. In the 13,200 and 14,400-volt class, a special range of taps, as previously described, was worked out to adapt a single transformer to both voltage classes.

Although most of the users in the 7,620-volt class actually operated at 7,620 volts to neutral, there existed some usage at 7,980 volts (or 8,000 volts) based on a line-to-line system voltage of 13,800 volts. To obtain the maximum benefits of standardization, it was decided to provide two $2^1/_2$-per cent taps above and below rated voltage on 7,620-volt units regardless of the secondary rating, thereby making one standard unit applicable to either system voltage.

The preceding discussion describes the basis for the selection of voltage and tap ratings on single-phase distribution transformers. The problems involved in a similar selection for 3-phase units were very much the same, although several additional factors were involved. The study and consultation process with users followed the same general pattern as that carried out for single-phase units.

Table VII shows the voltage and tap standards applying to 3-phase units, together with pertinent notes applying to load center applications and to 6,600-volt motor and control installations. In this table it will be noted that these 3-phase primary voltage ratings are substantially the same as those for single-phase units. On the other hand, since the single-phase units, up through 7,620 volts, are designed suitable for either line-to-neutral or line-to-line connections, the corresponding 3-phase units necessarily have such additional primary ratings as 4,160 volts Y, 8,320 volts Y, 12,470 volts Y, and 13,200 volts Y. The delta primary ratings included 2,400 volts, 4,160 volts, 4,800 volts (the 2,400×4,800 volts standard was omitted as being too complicated for 3-phase units), 7,200 volts, 12,000 volts, 13,200 volts, and 14,400 volts, the latter two being combined in one unit for ratings 75 kva and smaller. The 7,620-volt rating was omitted on the basis that there is no recognized usage on delta systems of that voltage.

The low-voltage ratings group themselves naturally into the well-established secondary voltages, 208 Y/120, 240 volts delta, 480 volts delta, and 600 volts delta. In ratings 75 kva and above, the 240-volt and 480-volt units were combined into a single unit rated 240×480 volts delta.

A feature requested by many operators and included in the standard is a 120-volt, reduced kilovolt-ampere lighting tap for such transformers 150 kva and smaller.

The growing usage of 480Y/277 volts or 600Y/346 volts in industrial plants was recognized by the selection of these Y-connected secondary units as alternative standards for such applications.

On 3-phase units in the 2,400-volt delta, 4,160-volt Y, 4,800-volt delta, and 8,320-volt Y classes with ratings 75 kva and smaller, the standard units were established without taps. On other ratings the general pattern was a 10-per cent total tap range, using four $2^1/_2$-per cent taps on ratings $112^1/_2$ to 500 kva and two 5-per cent taps on ratings 75 kva and smaller. This was a natural simplification since there are three times as many taps on a 3-phase unit as there are on a single-phase unit.

The location of the taps on these 3-phase transformers followed substantially the single-phase practice, the taps where provided being above and below rated voltage for transformers with secondary ratings of 240 volts, 480 volts, 240 × 480 volts and 600 volts. The taps for the 208Y/120 volts were obviously all below rated voltage, thereby matching the 120/240 volts and 240/120-volt tap position on the single-phase units.

Conclusions

In describing with as much detail as we have in this paper the step-by-step process of developing preferred voltage ratings for transformers, it is the authors' hope that we have shown convincingly that the resulting standards were not set up in a casual manner, but on the contrary represent the result of a tremendous amount of thought, work, and study carried out over a considerable period of time.

While it goes without saying that these standards are not perfect, nevertheless it is believed that the process of development was such that they will be adaptable to the majority of systems, at least to the maximum extent that can be expected from any set of standards.

While the adoption of these standards in no way prevents users from obtaining ratings other than those specifically listed, at the same time it is desirable that every possible effort be exerted to utilize these standards where they can be applied.

This will result in the greatest economy from an over-all standpoint and will prevent further tendency toward multiplication of voltage ratings, classes, and limits.

Finally, it may well be pointed out that a great deal of progress has already been made by the American Standards Association in incorporating into American standards the work and recommendations of the Joint EEI-NEMA Committee on Preferred Voltage Ratings for A-C Systems and Equipment.

Discussion

Howard P. Seelye (The Detroit Edison Company, Detroit, Mich.): As Chairman of the Power Company Group of the Joint Committee on Preferred Voltage Ratings, I was closely connected with the work of transformer standardization which the authors have described. They have done such an excellent job of compressing into a brief but clear and explicit statement the voluminous amount of survey, study, and discussion which was devoted to this work over a 10-year period, that there is little which can be added in that regard. I would like, however, to emphasize three points.

First, that the standardization of transformers was approached from a fundamental basis. The real needs of the users as shown by their operating voltages, in all their variety, were first thoroughly investigated. These were classified and then co-ordinated with certain proposed standards, taking full account of existing equipment, equipment being currently purchased, and the possibilities of moderate modifications in practice in some quarters to eliminate differences between requirements which were more apparent than real. The proposed standards were then carefully refined by reference again to the users and by cost studies of details.

It is believed that the final result represents as nearly a consensus of the true present requirements of the majority of users as it is possible to obtain.

A second point is that the Preferred Voltage Ratings set up a pattern, not only for present detailed standards being developed by the American Standards Association Committee (C57), but also as a basis for future modifications of the standards which may be found necessary in later years under changed conditions. This, again, is due to the fundamental approach.

The third point is that the standardization indicated cannot help but be of very material benefit in reducing the cost of producing transformers. This benefit will be pretty much in proportion to the amount of use which is made of the standards. The authors have brought out very clearly how many differences of opinion were resolved and answers reached which should be generally acceptable if clearly understood. A careful study of this paper is recommended to all those who wish to participate in the cost reductions possible by standardization.

Transformer Oil

E. D. TREANOR
FELLOW AIEE

E. L. RAAB
ASSOCIATE AIEE

THE HIGHLY complex nature of the material, the resulting difficulty in establishing significant tests for evaluation in reasonable time, and the varying conditions of use, have combined to make the study of oils used for the insulation and cooling of transformers a painfully slow process. It is the purpose of this paper to review some of the very extensive efforts made in this study and to draw at least tentative conclusions as to the present status and future possibilities of one of the most important materials in the design, manufacture, and operation of transformers.

Very great progress has been made since inception of the idea of a liquid insulation and heat carrier some 57 years ago. No detailed historical review is intended, but a very brief summary from the standpoint of one manufacturer may be of interest as there may be remnants of earlier practice even yet and memories of early troubles and later progress.

What was called number-6 oil was in extensive use in the first decade of this century in both transformers and switchgear. This and its predecessors, of which little record remains, were essentially commercial lubricating oils of paraffin base and with a high flash point (about 185 degrees centigrade), a viscosity of 100 seconds at 37.8 degrees centigrade and a pour point of −10 degrees. Engineers of outdoor switchgear found it necessary to adopt an additional oil of similar characteristics but with lower pour point—about −40 degrees centigrade—made from low freezing crudes. This was not used in transformers.

After 1910, the need for lower viscosity and better sludging characteristics led to venturesome use of lower flash-point material, and number 8 and number 12 (paraffin base), with characteristics as shown in Table I, came on the scene.

Table I

	No. 8	No. 12	No. 10
Flash point, °C	130	160	140
Fire point, °C	145	175	
Pour point, °C	−10	−10	−10
Gravity, 15.5/15.5°C	.84	86	
Viscosity, SUS at 37.8°C	45	66	52

About 1918, number 10 with intermediate characteristics was adopted to minimize the number of materials, although there was some overlapping due to the fact that some operators had established number 12 as a common material for transformers and circuit breakers.

About 1925, number 10-C was adopted largely to correct troubles with early conservator transformers used in northern climates. Made from low-freezing naphthenic-base crudes, its characteristics are generally stated as follows:

Flash point—minimum 130 degrees centigrade, average 133 degrees centigrade.
Fire point—minimum 145 degrees centigrade, average 148 degrees centigrade.
Pour point—Not higher than minus 40 degrees centigrade.
Viscosity, Saybolt universal seconds at 37.8 degrees centigrade—Maximum 58 seconds, average 57 seconds.
Free sulphur—None
Gravity at 15.5/15.5 degrees centigrade—0.88

With essentially unchanged basic characteristics, although improved from the sludging standpoint, number 10-C has been in use as our one standard for transformers since 1926 and was eventually adopted for the majority of our switchgear. This oil might be classed as oil produced by medium acid refining procedures.

Sludging troubles during the decade of 1920-1930 led to extensive experimentation with highly refined or "water-white" oil. We established a source for and made limited use of number 18 transil oil which had high flashpoint (170), viscosity (85), and freezing point (0 degrees). Eventually, it was concluded that there was little to justify its higher cost and other unsatisfactory characteristics. In passing, it is of interest to note that the extensive use of similar oils in other countries has been abandoned in favor of oils more nearly resembling our own.

Figure 1. Semisealed transformers—80 degrees centigrade top oil operation—effect of different impregnating materials on sludge formed

Paper 50-165, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 27, 1950.

Tests for Evaluation of Oil

During this long use of oil, great effort has been devoted by refiners, apparatus manufacturers, and operators to testing procedures by which various oils could be evaluated and the matter has been and is being continuously studied by the American Society for Testing Materials (ASTM) and other national and international bodies interested in the subject. Ability to judge an oil promptly by agreed-upon tests would obviously be of value in the purchase, application, and development of the material. A wide range of procedures has been proposed here and abroad. Many have been abandoned, many are still in use, and additions are proposed from time to time. It is unfortunate that out of all this effort, there is no unanimity as to the value of these procedures for predicting the life performance of an oil from its initially measurable properties and as to the parallel problem of determining the further usefulness of an oil which has been in service. It is hoped that the data and analysis herein may throw some light on the causes for this situation.

Nonaccelerated Life Tests

At the time this work was undertaken, commonly used tests included color, acidity, saponification, bomb (accelerated oxidation), sludge accumulation, and more recently interfacial tension and power factor have been added. As no entirely satisfactory correlation among these with operating results had been attained and as field data are nearly always indefinite because of uncontrolled conditions and uncertain records, it was decided that it might be of value to run small transformers under approximately normal load conditions indefinitely, so that in the course of time there would be data on actual transformers under controlled conditions and observation by good laboratory methods. These tests were not accelerated except by use of maximum temperature and continuous duty.

Some 30 small transformers with various insulations and treatments and a variety of oils have been under observation for about 15 years. Some of these units have insulating materials representative of those in apparently satisfactory use in power and distribution transformers during the past 20 years, but do not have the oil protective means such as sealing, conservators, and so on, which have been in common use during and preceding that period. Because of the absence of tight sealing, they represent past practice in ordinary distribution transformers or small power transformers, with breathers giving ample access to oxygen, and for brevity are called semisealed transformers throughout this paper.

The coil temperatures were maintained at approximately 95 degrees centigrade (average) and 105 degrees centigrade (hot spot) with a top oil temperature of 80 degrees centigrade, for the principal set of units, to simulate operation at full load in a 40-degree-centigrade ambient.

The procedure for measuring sludge formed, described in detail later, was intended to attain accurate knowledge of this quantity and has not, to our knowledge, been used elsewhere. In retrospect, questions arise as to any possible effect of the washing procedure and the abstraction and replacement with new oil of the samples used for some measurements. No precise answers can be given but it is believed that the conservative extrapolation used in the following discussion leads to valid conclusions.

These transformers after periods up to 15 years have shown various amounts of sludge. If some condition as regards sludging, acidity, and so on, is chosen as an arbitrary end of life, we may say that we have actually measured the full life of oil in a given transformer. For example, the transformer designated as having impregnant *A* in Figure 1 at the end of 15 years shows sludge at one per cent, acidity at one milligram KOH. Its condition after this run is illustrated in Figure 2. Its normal operating characteristics are little affected, but the presence of sludge is obvious and acidity is at a level sometimes considered as limiting. Prudent operation would indicate the desirability of cleaning up a transformer in such condition and replacing or reclaiming the oil. It is to be remembered that this transformer, which used normal oil and well-proved insulating materials, has operated continuously at 80 degrees centigrade top oil temperature with coils at about 105 degrees centigrade (hot spot), conditions representing full load at maximum ambient temperature.

Calculations indicate that under average operating conditions of load and load factor in service, the oil life shown in the

Figure 3. Transformers under life test

Figure 5. Semisealed transformers—80 degrees centigrade top oil operation—effect of different impregnating materials on measured acidity

continuous run would mean a life of between 20 and 30 years in service before attaining the criterion chosen. As compared with this, the life of class-*A* solid insulation continuously operated at 105 degrees centigrade has been estimated at from five to seven years or at an operating life of from 10 to 14 years on the basis of extrapolation used in the foregoing. This life is, of course, on the basis of an arbitrarily chosen relation of some mechanical property of the material at the end of life to that at the beginning (usually some percentage of initial tensile strength). In the light of common operating experience and the condition of these test units, this figure of 10 or 14 years does not seem realistic, and it seems reasonable to assume that the practical life of the solid insulation is at least as long as that of the oil as shown in these tests.

Some of the transformers under test were subjected to overloads and short circuits after 15 years of test, and the results support the view that the solid insulation, while much embrittled, is intact and the transformers in operating condition.

It should be evident that no one can with certainty set up an estimated or expected life of the oil or solid insulation materials of a transformer in service. Fundamental data on both materials can only be stated on arbitrarily chosen bases. The good mechanical performance of the small transformers reported upon is not likely to be sharply indicative of the performance of power transformers similarly aged. Furthermore, it should be evident that appreciable overloading will have the effect of aging the solid insulations relatively more rapidly than the oil because of the higher temperatures attained in the coils. The well-established laws governing rates of aging show that a change of temperature of the order of eight degrees centigrade can halve or double a life determined by a particular set of conditions. Our purpose here is merely to show that results obtained from very long runs, at normal load under controlled conditions on transformers using good materials, are in line with experience on this type of transformer and to throw more light on things which will affect the life of a transformer.

Life Test Method and Procedure

The 5-kva transformers were operated continuously at 60 degrees centigrade, 80 degrees centigrade, or 100 degrees centigrade top oil temperature. This was achieved by energizing the units in pairs at 230 volts on the low side and paralleling the high sides with the ratio adjusters set apart by two positions. This produced about 120 per cent of full-load current input in each unit. In some cases, units were blanketed with asbestos to realize the desired temperature. Normally, no-load-loss measurements were made semiannually at operating temperature. Power-factor measurements were made annually with a Schering high-voltage bridge at operating and room temperatures. Periodically, oil samples were withdrawn and various characteristics measured. Core and coil assemblies were withdrawn from the tank for inspection and photographing at stated intervals, at which time the total precipitate, total sludge, oil-soluble sludge, and material other than oil sludge was determined. Figure 3 shows some of the transformers under life test. Figure 4 illustrates two typical transformers operating as a pair.

Method of Test

Regarding acidity, the oil acidity is measured in accordance with ASTM methods. In sludge determinations, the transformer was cooled to room temperature, and the core and coils were untanked and drained while being suspended over the tank. Sludge adhering to the core and coils was very carefully washed into the main body of the oil in the transformer tank. The oil and sludge were stirred mechanically until the sludge was evenly distributed throughout the oil and two representative samples of the suspension were taken while the stirring was in progress.

The total precipitate was determined on one sample by washing the sludge with naphtha, drying, and weighing. This included all the precipitate contained in the sample plus that oil sludge which was precipitated out of the oil during the naphtha dilution. The total oil sludge and material other than oil sludge was determined by removing the oil sludge with successive acetone washes. The residue was classed as foreign material other than oil sludge. Percentages are based on the known weight of the oil and the solid material.

Figure 6 (left). Semisealed transformers—80 degrees centigrade top oil operation—effect of modifications of process using impregnant B (see Figure 1) on sludge formed

Figure 7 (right). Semisealed transformers—80 degrees centigrade top oil operation—effect of modifications of process using impregnant B (see Figure 5) on measured acidity

Figure 8. Semisealed transformers—effect of temperature levels for two impregnants on sludge formed

The oil-soluble sludge was determined on a separate sample and is that part of the total sludge which dissolves in the oil at the operating temperature of the transformer. This sample was heated for 48 hours, with shaking, at the operating temperature of the transformer and was then filtered at this temperature to remove excess sludge and foreign material. A weighed sample of the filtered hot oil was then cooled and the sludge determined in the usual manner.

Data on Semisealed Transformers with Normal Oils

Transformer operators are primarily interested in the sludging tendency and the acidity of the oil in their apparatus as these are the characteristics which may actually affect operation. Most other types of tests are a means of gauging changes in the oil quality which are ultimately reflected in increased acidity or sludge deposition, or both. One of the factors influencing the life of an oil as gauged by the amount of sludge deposited in the transformer is the type and method of application of coil-impregnating materials. For the purposes of these studies, 1.0 per cent of sludge by weight of the oil charge has been chosen as the end of life. Figure 1 compares the total oil sludge formed in three similar 5-kva transformers treated with dissimilar types of impregnants designated as *A*, *B*, and *C*. These transformers were operated continuously at 80 degrees centigrade top oil temperature under semisealed conditions.

A common field criterion for oil life is the measurement of the oil acidity. Some operators take the neutralization value of 1.0 milligram of KOH per gram of oil acids produced by normal oxidation as the criterion for reclaiming or changing the oil. Figure 5 compares the oil acidity formed during the life of the three units previously described. In this case, the acidity yields relatively the same information, with impregnants *A* and *C* showing the longest oil life.

In view of the differences shown in life characteristics of the oil when various impregnants were used, a series of units were started with variations of impregnant *B*. Figure 6 illustrates the increased life secured by the modification designated as *B-1* as gauged by the amount of sludge formation. Units impregnated with *B-2* and *B-3* have not been on test sufficiently long to draw any firm conclusions, but at this date do not appear to be as satisfactory. Figure 7, using neutralization number as the guide, again designates impregnant *B-1* as a decided improvement.

In an effort to find the effect of temperature on 10-C oil in contact with several of the more desirable impregnants a series of transformers were operated at 60, 80, and 100 degrees centigrade top oil temperature. Figure 8 shows a typical relation secured as reflected by the amount of sludge formed. It is of interest to note that in a rough sense the 7–10 degree centigrade rule is true in that for approximately each 7–10 degree centigrade rise in temperature, the amount of sludge formed is roughly doubled. Even though the 100 degrees centigrade operating unit containing impregnant *B-4* yielded over 8.5 per cent oil sludge after 12 years on life test, it is still operating satisfactorily and shows no signs of approaching failure. Figure 9 compares the oil acidity formation with life of the same transformers under varying top oil temperature operation. Here, the 7–10 degrees centigrade rule does not seem to hold nor does the value of 1.0 milligram of KOH per gram of oil acidity consistently correspond with the value of 1.0 per cent sludge in terms of years of oil life. This may be due to the effect of soluble materials other than oil oxidation products being present in the oil and will be dealt with in another part of this paper. Relatively speaking, however, impregnant *A* appears to be more desirable than impregnant *B-4*, and the effect of increased top oil temperature is reflected in increased oil deterioration for either impregnant.

The question might be asked as to whether or not the effect of various impregnants on oil life has been noted under actual service conditions. Figure 10 illustrates the effect of several types of impregnants on oil life as judged by the measured oil acidity of samples taken from semisealed transformers operated under severe service conditions of load and ambient temperature. Impregnant *D* is an oxidizing-type varnish long since discontinued, that apparently was incompletely cured before coming in contact with the oil and, as a result, oil deterioration proceeded at a rapid rate as shown by the acidity gain and observed sludge. Similar units refilled with new 10-C oil after several years of preliminary operation yielded a much lower acidity gain coupled with an apparent leveling off. It is presumed that the initial run with the original oil more completely cured the impregnant and that the oil-soluble com-

Figure 9. Semisealed transformers—effect of temperature levels for two impregnants on measured acidity

Figure 10. Semisealed transformers—service operation under conditions of severe load and ambient temperature on measured acidity

ponents were largely removed when the oil was changed. Impregnant *A*, while a decided improvement over impregnant *D*, still showed a marked improvement with a second oil filling after several years of preliminary operation of the transformers. This may be due to the removal of detrimental oil-soluble materials during the operational period with the first oil filling. Except for the original oil filling of the transformers containing impregnant *D*, all other variations are well below the neutralization value of 1.0 milligram of KOH per gram of oil. The curves shown in Figure 10 are in each case average values for similar transformers operated under similar conditions in the same location.

It should be noted that throughout this study no attempt has been made to draw smooth line curves in that the determined points occasionally tend to be erratic. This is particularly true for the measured oil acidity values. Figures 5, 9, and 10 indicate that in general the oil acidity tends to level off after an early initial rise and dependent upon operational temperatures, types of transformer impregnants, and so on, the oil acidity value remains roughly constant for long periods of time. The initial early rise may indicate the presence of some oil-soluble material which either promptly produces acidic molecules or influences the production of acidic molecules through oil deterioration.

Oil Contamination Studies

A number of years ago, it was recognized that oil life may be influenced to a large degree by the various transformer materials in contact with it and that some materials may also be affected adversely by being in contact with the oil. Since that time, all materials used in our practice in contact with 10-C oil have been examined under accelerated conditions for physical and chemical contamination of the oil. The effect of the oil on the material is also studied, and no material is used whose electrical, physical, or mechanical properties are affected adversely by being in contact with the oil. Naturally, all types of transformer oils are not affected in a similar fashion by the various solid constructional materials used nor do they all exert the same effect on these various materials.

The 10-C oil after the accelerated aging period is examined for color and acidity changes, as well as various sludging propensities. The solid material is examined for various physical, mechanical, and electrical properties. Additional tests are performed as dictated by the type of material under examination.

Some of the more important findings of this section of our data, together with some unreported data, may be summarized as follows:[4]

1. Oil life as evaluated by sludge formed or acidity gain may be influenced to a large degree by the type and method of application of impregnating materials. This has also been found to be true for transformers operating under actual service conditions.

2. The manufacturer's choice of materials which are to be in contact with the oil may reduce the oil life.

3. The operating characteristics of the transformers studied were not seriously affected by sludge deposits of the order of 1.0 per cent by weight of the oil charge which for noninhibited 10-C oil corresponded in general to an oil acidity value of approximately 1.0 milligram of KOH per gram of oil.

4. Sludge deposits in excess of 7 per cent by weight of the oil charge have not resulted in failure of test transformers.

5. The rate of sludge formation is approximately doubled for every 7–10-degree centigrade rise in top oil temperature throughout the temperature range of 60 to 100 degrees centigrade.

6. For 10-C oil, the rate of sludge formation proceeds in general at a uniform rate.

7. In general, oil characteristics for 10-C oil, such as viscosity, gravity, power factor, saponification, sludge accumulation, resistivity, and so on, while reflecting changes occurring in the oil during its life, are erratic and appear to have little value as indicators of the rate of sludge formation. Acidity levels and color values tend to indicate when sludging is occurring to any marked degree, although the highest acidity level does not necessarily indicate the greatest rate of sludge formation. This apparent discrepancy is attributed to the possible influence of small amounts of certain oil-soluble components secured from various solid insulations on the acidity gain without a corresponding gain in sludge formation. In general, however, an oil acidity of 1.0 milligram of KOH per gram of oil approximately corresponds to 1.0 per cent of sludge formed for 10-C oil.

Figure 11. Records of acidity of normal oil in 12 sealed network units during 13 years of service—nitrogen atmosphere substantially maintained

Figure 12. Semisealed transformers—80 degrees centigrade top oil operation—effect of various inhibitors in 10-C oil on sludge formed

8. Oxidation studies may preclude the use of a poor oil, but even a good oil may yield bad service when in contact with solid insulation and materials of poor choice.

Oil Protective Means

Beginning with the conservator, there has been extensive use during the last 35 years of various structures in power transformers designed to limit or prevent the entrance of oxygen, dust, fumes, and water, and to minimize or prevent evaporation. More recently, there has been a trend toward the use of the simplest of these structures in distribution transformers, that is, simple sealing with a gas space sufficient to take the ordinary pressure range. It is not proposed to attempt any comparison of the virtues of the various methods of excluding oxygen. This will doubtless be under continued study in the future. There seem reasonable grounds for the assumption, however, that with these methods and with application of what is known as to materials and processes, the problem of oil as a limiting factor in the life of transformers is a diminishing rather than increasing one.

The tests reported herein throw no light on the matter since none of these structures were used. Indications from field service and laboratory studies indicate, however, that some of these methods have the possibility of extending the life of oil and solid materials by perhaps 50 per cent.

Oil Life When Oxygen Is Minimized or Eliminated

All of the data presented so far have been for transformers operating under semisealed conditions. It is generally recognized that the rate of oil deterioration is materially reduced by various mechanical means of preventing the oil from coming in contact with atmospheric oxygen. Such methods of oil preservation can be classified as conservator protection, hermetic sealing, gas-oil sealing, and nitrogen blanketing. These modern methods of oil preservation have been markedly successful as evidenced by the lack of service complaints due to oil deterioration.

Some service operational data on oil in sealed network units operating under a substantially maintained nitrogen atmosphere are shown in Figure 11. It is noted that the oil acidity for an average of 12 transformers is less than 0.24 and any one unit yielded a maximum oil acidity of 0.40 milligram of KOH per gram of oil. These values are well below the neutralization maximum of 1.0 which is used as a guide by some operators and much less than the acidity values secured under 60 or 80 degrees centigrade continuous semisealed life test conditions for a period of 14 years. (See Figure 9.) Based on the assumption that normal service would yield an oil life of about twice that secured under the accelerated life test conditions, we can project an oil life for transformers with oil protective means far in excess of the expected oil life under semisealed conditions.

Inhibitors

Successful use of inhibitors in other fields, particularly rubber and lubricating oils, led very soon to consideration of similar use in transformer oil. Two objectives were considered. One was to extend the life of normal oil on the assumption that this was not sufficient. The second was to see whether less refined and hence less expensive oils could be made by the addition of inhibitors to give life of the same order as oils properly refined for maximum life. Neither objective has as yet come to fruition. The primary objective of increasing life becomes questionable in view of previous conclusions that transformers of satisfactory design and materials using normal oil and oil protective means will give life equal to or greater than that of the solid insulations. The objective of obtaining oils of lower cost by use of inhibitors in less refined oils is not now believed to be hopeful.

Among the small semisealed units previously referred to were several in which inhibitors were used and directed at each of the objectives mentioned above. Oils underrefined as compared with normal transformer oil, and which had some hope of providing lower costs, were treated with inhibitors which had been sufficiently

Figure 13. Semisealed transformers—80 degrees centigrade top oil operation—effect of various inhibitors in 10-C oil on measured acidity

Figure 14 (left). Semisealed transformers — 100 degrees centigrade top oil operation—comparison of sludge formation in 10-C oil to that formed in several commercially available inhibited oils

Figure 15 (right). Semisealed transformers—100 degrees centigrade top oil operation—comparison of measured acidity in 10-C oil to that formed in several commercial inhibited oils

studied at the time to be hopeful. These oils are referred to as distillates in the following data. They were run with other transformers having normal oil similarly treated, and with other variations.

Practical Considerations in Using Inhibited New Oil in New Apparatus

Some presently available inhibitors have properties which will justify careful study from the standpoint of economics and the complexities they unavoidably introduce. If there were available today one or more inhibitors which were considered to be completely satisfactory in a technical sense, the decision to use inhibitors in oil in new apparatus would still be largely influenced by a number of practical considerations for which the present state of knowledge is quite limited. The suitability of such oils for circuit breakers and bushings, the increased cost as opposed to the expected gains, the actual need, if any, in most transformers of modern oil protective design, the eventual problem of reclamation and disposal of the reclaimed inhibited oil, and how to predict and test for its service life must be considered. The compatibility of inhibited oils, their limitation to a practical number, and the maintenance of reasonable interchangeability apparently requires much further study. New inhibitors and inhibited oils are being made available and additional ones are in the offing. Data presented indicate that careful consideration must be given not only to the inhibitor but to the base oil as well. It will take much time to evaluate these oils and inhibitors and to arrive at conclusions as to their merits. The problem is not just whether oil can or cannot be successfully increased in life by the use of inhibitors. It can, of course. The problem is to evaluate the over-all economic, dielectric, chemical, and practical advantages and hazards presented by the use of these oils during years of commercial service.

Semisealed Transformers with Inhibited Oils

Figure 12 compares the effect of various inhibitors in 10-C oil on the sludge formed. The 5-kva transformers were operated at 80 degrees centigrade top oil temperature under semisealed conditions. Of particular interest is the fact that 10-C oil with inhibitor *A* is apparently better than 10-C oil alone from a sludging standpoint in the early stages of the oil life, but is not as effective and may even tend to be detrimental during the later stages of aging. This indicates the necessity for caution in rapid evaluation of an inhibited oil.

Inhibitors *B* and *C* are very effective and approximately equivalent, being well below the 1.0 per cent sludge figure after 14 years of accelerated life. Figure 13 compares the acidity development of these oils. Again we note that inhibitor *A* is quite effective up to six years of accelerated life, but rises rapidly thereafter in terms of acidity and yields values at least as high as the values later obtained by 10-C oil alone. The 10-C oil with inhibitor *B* shows an early sharp acidity rise followed by a leveling off, and viewed in this light is no improvement over 10-C oil alone. The 10-C oil plus inhibitor *C* is a definite improvement over 10-C oil alone whether gauged by sludging or acidity.

Figure 16. Standard 15-kva transformers with pipe breathers added—100 degrees centigrade top oil operation—comparison of precipitation sludge formed in oil samples from various inhibited oils and 10-C oil

Figure 17. Standard 16-kva transformers with pipe breathers added—100 degrees centigrade top oil operation—comparison of the measured acidity formed in various inhibited oils and 10-C oil

During the course of these studies, a number of inhibited oils have become commercially available. Figure 14 compares three of these inhibited oils to 10-C oil under 100-degree centigrade top oil operation in semisealed transformers of 5-kva design. While it is too early to draw any definite conclusions, the amount of sludge deposited in each case by the inhibited oil is greater than that produced by the 10-C oil alone during the early accelerated life of the transformers. Figure 15 demonstrates the measured acidity secured for these same oils. Of particular interest is the runaway acidity development demonstrated by inhibited oil *D*. In no case, during the early stages of life are any of these oils superior to 10-C oil alone. In the case of inhibited oil *D*, the transformer had to be removed from service due to a runaway temperature rise. The oil after 1.7 years of life had changed in viscosity from 62 to 125 Saybolt seconds taken at 37.8 degrees centigrade. Along with this rapid rise in acidity, the character of the sludge deposited on the core and coils was of a gummy adherent nature which could not be removed by normal oil washing methods. This type of sludge is characteristic of an overly refined base oil. Figures 16 and 17 throw additional light on this type of oil. In these tests, 15-kva transformers with pipe breathers added were operated at 100 degrees centigrade top oil temperatures. Figure 16 compares the precipitation sludge (that is, sludge secured with the oil sample when such samples were periodically withdrawn from the transformers) of several commercially inhibited oils to 10-C oil and to 10-C oil containing inhibitor *C*. Here again we note that inhibited oil *D*, while behaving in a superior fashion in the earlier stages of its life, ran away after 43 weeks of accelerated life and at 73 weeks life was depositing more sludge on a weight basis than any of the other oils. Inhibited oil *F* behaved in a superior fashion for a short time but broke sooner than inhibited oil *D*. The 10-C plus inhibitor *C* again reflected a gain over 10-C oil alone and yielded more resistance towards sludging under prolonged life-test conditions. The table contained in Figure 16 gives the total oil sludge secured in the transformers after 73 weeks of accelerated life, at which time the tests were discontinued. Here we find that 10-C oil plus inhibitor *C* yielded only one-third to one-quarter the amount of sludge as compared to the other oils. The sludge determination of 2.30 per cent for inhibited oil *D* is listed as being approximate in that it was impossible to remove the gummy varnish-like sludge from the coil sections without also removing cellulosic insulation. From previous data, the amount of sludge adhering to the core and coils was estimated to be approximately 20 per cent of the total formed on a weight basis. Inhibited oil *F* is characterized by early sludge formation coupled with a rapid rate of sludge deposition. Figure 17 shows the oil acidity development for this same series of transformers. Relatively speaking, the acidity measurements classify the four oils in the same manner as do the precipitation sludge values. Again we note the early stabilized period for oil *D* followed by an extremely rapid rise in acidity whereas the other three oils appear to be reaching a relatively stable acidity level.

Inhibited oil *D* exhibits the characteristics of an overly refined base oil to which an effective inhibitor has been added. Figure 18 compares the measured acidity of an uninhibited water-white oil, 10-C oil, and inhibited oil *D* during open beaker agings at 75 degrees centigrade of impregnated stamp capacitors operating under 812 volts per mil stress. While 10-C oil shows a slow steady increase in acidity over a 55-week period, inhibited oil *D* yields the characteristic runaway acidity condition which parallels that secured much earlier during this aging study by the water-white oil. The oil viscosity for inhibited oil *D* and for the water-white oil nearly doubled during this period whereas the 10-C oil viscosity increased very slightly. The characteristic gummy adherent sludge was deposited for both the water-white oil and inhibited oil *D*.

A series of 5-kva transformers were operated at 80 degrees centigrade top oil temperature containing a semicrude distillate with and without various added inhibitors. These units were run under semisealed conditions. Figure 19 com-

Figure 18. Comparing the measured acidity of a water-white oil to that formed in inhibited oil D and 10-C oil during open beaker agings of impregnated stamp capacitors operating under 812 volts/mil stress

pares the total oil sludge formed by these oils to that formed by 10-C oil. After nearly 14 years on accelerated life test, the distillate oil is exhibiting rapid sludge formation whereas the same crude distillate oil with inhibitor *B* appears to be almost equivalent to 10-C oil. Inhibitor *A* is not as effective as *B* in retarding sludge formation. When we look at Figure 20 which compares the acidity development for these same oils, we find that inhibitor *B* is not as effective as *A*. In fact, we find that the acidity level invariably is higher than that obtained for the semicrude distillate alone. We again note the characteristic early rise in acidity with a subsequent leveling off. In terms of acidity alone, the distillate oil has deteriorated only slightly more than the 10-C oil. Figures 21 and 22 illustrate the performance of a series of inhibited oils operating at 60 degrees centigrade top oil temperature.

Again it is interesting to note the effect of actual service operation on some of the various inhibited oils under discussion. Figure 23 illustrates the behavior of a series of inhibited and noninhibited oils as judged by oil acidity formation while operating in service under conditions of severe load and ambient temperature. These transformers are of semisealed design and all units were given a preliminary operation of several years with 10-C oil before being filled with the oils being reported. All values given are average values for a series of similar transformers operating under similar conditions at the same location. No actual sludge data are available, but from our controlled accelerated life studies, we would predict from the acidity curves that on a comparative basis, the oils would be graded in the following fashion in terms of increasing amounts of sludge present after 13 years of life: water-white oil; 10-C oil; 10-C oil plus inhibitor *B*; semicrude distillate oil plus inhibitor *B*; 10-C oil plus inhibitor *A*; and semicrude distillate oil plus inhibitor *A*. While the water-white oil appears to be behaving satisfactorily from the standpoint of acidity, the fear is always present that such an oil will exhibit the runaway characteristics reported under Figure 18. It has been noted in our controlled accelerated life-test studies that the acidity value of 1.0 milligram of KOH per gram of oil does not correspond to a total oil sludge value of approximately 1.0 per cent for inhibited oils in every case, but may reflect either an approximate value of one per cent or a much lower value. The sludge value was never more than approximately one per cent in any instance for a corresponding acidity of one milligram of KOH per gram of oil for the inhibited oils. From these studies, it would also be predicted that every oil reported on Figure 23 has formed less than one per cent total oil sludge in their respective transformers after 13 years of life.

Figure 20. Semisealed transformers—80 degrees centigrade top oil operation—comparison of measured acidity in 10-C oil to that formed in a distillate with and without inhibitors

Figure 19. Semisealed transformers—80 degrees centigrade top oil operation—comparison of sludge formation in 10-C oil to that formed in a distillate with and without inhibitors

While the reported data on inhibited oils constitute only a fraction of the work done, some observations and conclusions may be drawn from the data presented.

1. Some inhibitors when added to 10-C oil may retard sludge formation during the oil's early life, although the total sludge formed in the oil's later life may be equal to or slightly more than that produced by the 10-C oil without an added inhibitor.

2. When viewed from the sludging standpoint alone, 10-C oil can be successfully inhibited against sludge formation for long periods of time. This does not mean that such inhibited oils are completely satisfactory in all characteristics nor economically feasible to use.

3. Some of the oil inhibitors when added to 10-C oil retarded sludge formation but promoted acidity formation to a greater degree than is produced by the 10-C oil without an added inhibitor.

4. In general, 10-C oil containing an inhibitor, still shows the characteristic initial rise in acidity which is subsequently followed by a long period when the acidity is comparatively constant. This initial rise in acidity may be due to the effect of oil-soluble material from solid insulation.

5. Several commercially available inhibited oils do not exhibit any superiority over 10-C oil when viewed from the sludging standpoint during the early stages of the oil life under semisealed transformer conditions. Other commercially available inhibited oils which were examined were definitely inferior to 10-C oil when aged for long periods of time under semisealed conditions.

6. One commercially available inhibited oil (inhibited oil *D*) has been shown to exhibit the characteristics of an overly refined base oil to which an effective inhibitor has been added. This oil, however, breaks badly at some point in its life with a runaway acidity and sludge development. The type of sludge formed is also of a different character from that produced by more conventionally refined oil, being of a gummy adherent nature. These characteristics conceivably might make it difficult for an operator to predict when this oil was nearing the danger stage, and should

he already have secured sludging, he would find it difficult, if not impossible, to clean the core and coils.

7. The measurement of the precipitation sludge, which is the sludge secured when oil samples are periodically withdrawn from transformers under study, while a valuable index to oil condition, is rarely indicative of the amount of sludge in the transformer.

8. Short-time laboratory tests with inhibited oils can lead to erroneous conclusions as to the behavior of the oils in service in terms of useful oil life.

9. Various inhibited oils operating under actual service conditions for over 13 years are exhibiting the expected characteristics which would be predicted from the controlled accelerated transformer-life studies.

10. The 7–10-degree centigrade rule previously cited wherein the rate of sludging for noninhibited 10-C oil approximately doubles for each 7–10 degrees centigrade rise in temperature does not hold quite as well for inhibited oils.

11. Laboratory oxidation studies and initial oil characteristics on new inhibited oil yield little indication of the oil's performance in service in terms of years of useful oil life. While such tests may, to some extent, indicate the type of base oil, its degree of refining, and the eventual rate and type of sludge and acidity formation, the inhibitor life period may be considerably shortened by service conditions and the materials with which the oil is in contact.

12. Neither sludge nor acidity formation proceeds at a uniform rate for all inhibited oils and may accelerate markedly when the inhibitor life is ended.

Reclamation of Aged Oil

While these data seem to establish a fairly long life even for semisealed units, there are in the normal course of operation a percentage of transformers, severely overloaded, exposed to unusual ambient temperatures, having past design defects in the way of materials, hot cores, inferior oils, and so on, or failed coils, or simply very old, which give operators constant indication of a problem with a volume of oil, not large as compared with the total in use, but sufficient to justify study of reclamation methods and to raise the fear on the part of operators and apparatus manufacturers that the problem is increasing. We have not found wholly satisfactory reclamation methods but have for many years practiced the fuller's earth reclamation of small quantities of oil where it could be blended or diluted with new oil to such an extent that the objectionable effects of such refinement are lost. New oil contains a certain amount of so-called natural inhibitors which vary, dependent upon the type and the degree of refinement of the oil.

Any refinement by activated adsorbing

Figure 22. Semisealed transformers—60 degrees centigrade top oil operation—comparison of measured acidity in 10-C oil to that formed in 10-C oil plus various inhibitors and a distillate oil plus various inhibitors

Figure 23. Semisealed transformers—service operation under conditions of severe load and ambient temperature—measured acidity—units refilled with oils as designated after preliminary operation under 10-C oil

agents tends to remove these inhibitors with a resultant oil less stable as regards oxidation. The procedure cited has not seemed a panacea and has been recommended to operators in only a few special cases.

The apparatus, the supervision, and the economics of the process all present problems which require much engineering, and which have justified less effort on the part of the apparatus manufacturer than the primary problem of producing new apparatus which will give very long life of the oil.

Recently, reclamation processes based on treating to a suitable degree with fuller's earth and then adding an inhibitor have been tried. Suitably controlled, it would seem that they should be useful in extending the life of old oil and old transformers.

Conclusions

The life of oil in transformers is substantially influenced by the materials in the transformer, and continuing research and improvement in these materials are essential to get maximum life from oil.

The life of oil in transformers, having well chosen materials and suitable means for excluding oxygen, is of the order of the life of the solid insulating materials.

In view of the preceding conclusions and even assuming that entirely suitable inhibitors are available, their use in new transformers does not yet seem of proved value. We do not believe that final conclusions can be drawn at this time, but results of great importance do not seem to be indicated.

Use of inhibitors in reclamation processes for badly oxidized oil may be of value. Probable costs of the whole process is in the range of 8 to 15 cents per gallon and will indicate to what extent these processes will show economy.

Much has been learned from these tests which will be of value in guiding future work. Some indicated improvements in material and structure of transformers have already been made and others are under study.

Discussion

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.) This paper is a very interesting review of past and present problems with regard to insulating oil, and helps to a better understanding of the progress which has been made in conventional oils over the years. The information on the performance of inhibited oils is of special interest, because the need of superior oils has increased on account of higher operating temperatures in recent years. This interest was also indicated some 12 years ago in connection with the research on insulating oils that was sponsored by the AIEE and the Engineering Foundation and was conducted at the Massachusetts Institute of Technology for several years.

It is of interest to note that precipitation sludge is rarely indicative of the amount of sludge in the transformer. Unfortunately, this is the only sludge test the operator is able to make in periodic checks of transformers, as dismantling to obtain the total sludge is obviously impractical. In Figures 1, 8, 12, and others, the total amount of sludge is shown at various times during the aging of the transformer. Does this mean that at the time of each sampling the transformer was dismantled and the core thoroughly cleaned in order to dissolve the deposited sludge into the oil for the purpose of obtaining total sludge content?

The possibility of accelerated or of rapid deterioration of some inhibited oils after the inhibitor is used up, suggests the need of a reliable test by which the operator can predict the time when replacement of inhibited oil is necessary.

We have found it both necessary and feasible in Chicago, from an economic standpoint, to increase the loading of transformers substantially with resulting temperature increases of 10 to 15 degrees centigrade over the oil temperatures which prevailed up to 1937. Assuming that the life of insulating oils was then of the order of 20 to 30 years, as mentioned by the authors, then on the basis of the 7- to 10-degree rule mentioned in the paper, the life of the oil with these temperatures would be only one-half to one-quarter of the previous life, or as low as five years.

We have found various evidences that accelerated aging of transformer oil, including accelerated sludging, is actually occurring in existing transformers. Furthermore, we have found that after deteriorated oil is replaced by new oil, the replacement oil deteriorates at a much faster rate than the original oil due to residual contamination products in the transformer. Since the labor cost is a large portion of the total cost of oil replacement, a superior oil which would reduce or eliminate frequent oil replacement would be economically very attractive. Also, it would decrease the amount of field work necessary at odd hours in connection with transformer maintenance.

The results of the authors on tests of inhibited oils are very interesting, especially since they show the need of long-time tests to properly evaluate such oils. We agree with the authors that short-time laboratory tests may lead to erroneous evaluation. We have made aging tests of conventional oil and of inhibited oils in old and new open-type distribution transformers for a period of 42 months. The results showed a superiority of the inhibited oil over the conventional oil of the order of 2-to-1 for the old transformers, and of 3-to-1 for new transformers. In short-time laboratory tests, which do not use transformers, the ratio was much higher.

On the basis of our test results and economic studies, we have made the decision to use inhibited oil as replacement oil in existing transformers, when replacements become necessary due to excessive deterioration of the oil now in the transformers. For this purpose, only new oil with the inhibitor added by the suppliers is to be used. We are in the process of making aging tests of inhibited and conventional oils for the purpose of determining the relative performance and expected life in transformers protected by a conservator or by a nitrogen seal. New distribution transformers are used for this investigation. This series of tests relates to present-day designs of transformers.

E. D. Treanor and **E. L. Raab:** In reply to the interesting comments of Mr. Halperin, it is unfortunately true that precipitation sludge is not an entirely satisfactory indicator of the total sludge formed. We adopted the somewhat troublesome method of periodic untanking of the transformers, brushing and washing the deposited sludge into the oil before measurement. It is, of course, not a very practical method for field use. It is possible that interfacial tension now under active study may ultimately prove to be a satisfactory, although indirect, indicator of sludge.

It is, of course, quite true that an increase in oil temperature will decrease its life, roughly by half for each 7 to 10 degrees of increase.

It may be well to recall that the same rather general chemical laws apply to the solid materials in the transformer, and the temperature of some of these solid materials will increase more rapidly than that of the oil and, hence, their rate of degradation will be greater relatively than that of the oil.

The economics of high-load levels and shortened life of transformers is a study for operators in which the manufacturer is a detached, but very much interested, observer.

We believe it is fairly well established that sludge, particularly soluble sludge will catalyze new oil and decrease the effectiveness of inhibitors, so that thorough washing of old transformers is desirable if it can be practiced.

A review of our test data does not offer confirmation of the superiority of inhibited oil which Mr. Halperin reports. This is probably due to the longer duration of our tests and to differences of interpretation and criteria, which we hope can ultimately be reconciled.

The suggested method for a reliable test by which the operator can predict the time when replacement of inhibited oil is necessary is under study by American Society for Testing Materials for new oils, and some modification of any practical method could probably be applied to used oils.

Interexchange Tandem Trunking in the Los Angeles Metropolitan Area

W. F. PFEIFFER
ASSOCIATE AIEE

Synopsis: Twenty-four years have elapsed since the first large-scale machine switching tandem system was designed and installed for service in Los Angeles. As an intermediate switching center, the tandem office enabled operators to use the dial method of operation for establishing interexchange telephone connections over the associated trunking network. During the intervening years, it has facilitated the rapid handling of telephone calls between the various communities in and around the city. Step-by-step tandem equipment was employed and as the volume of calls grew, the trunk capacity was increased by installing additional switching equipment. In 1946 it became evident that the abnormal rate of growth required additions substantially beyond the practical size limit of the step-by-step tandem unit. To solve the resulting problem, it became necessary to reorganize the tandem trunking system and select a multiunit tandem switching plan. It also provided an opportunity to consider the application of the more recently developed crossbar tandem switching system. This paper reviews the factors affecting the general problem of interexchange trunking which have led to the development of the present tandem network in the Los Angeles metropolitan area. It describes the major elements of a system which now employs a total of five tandem switching units, three of which are crossbar tandem offices.

THE provision of telephone service between the communities of a large metropolitan area presents many problems. Appropriate quantities of switching equipment and cable pairs must be provided to carry the expected loads and to perform the functions required for interconnecting telephone users. The resulting plant design must be such that satisfactory service can be provided at a minimum cost to the subscriber. To meet these objectives, operating methods are required which will facilitate the rapid handling of high volume calling. Economical plant design requires efficient operation and an economic balance between the cost of arrangements employed to improve plant efficiency and the value of the savings obtained.

Since forecasts of the volume and distribution of future traffic are the bases for plant design, unpredictable variations in traffic growth and changes in telephone practice are some of the elements of risk associated with planning for growth.

Tandem operation provides one of the principal devices available for improving operating methods and plant efficiency. As an auxiliary switching center it is the hub of trunk plant in a large highly-developed switching network, interconnecting central offices and operating centers. In this capacity it is sensitive to all the unpredictable and changeable elements of advance telephone planning.

Many types of tandem offices are employed throughout the United States and have been described quite thoroughly elsewhere.[1] A step-by-step machine switching tandem system, installed for service in Los Angeles in 1926, was described by F. O. Wheelock and E. Jacobsen in a paper in 1928.[2] A more recent contribution toward the solution of interoffice trunking problems has been the introduction of the crossbar tandem system.

In Los Angeles, where large scale dial tandem trunking is employed only for interexchange traffic, the volume of calls has grown beyond the capacity of the original tandem unit and a multiunit tandem system now is in operation. The accelerated rates of growth in recent years have required an ever-increasing effort to:

1. Provide for total growth in interexchange service.
2. Make adjustments for changes in the rate of growth in individual trunking paths.
3. Provide for changes in the central office numbering plan in order to permit the extension of subscriber dialing on a prefix and number basis.
4. Provide equipment to match a trend toward finer gauge cable pairs.
5. Provide trunk terminating equipment to match the various types employed in connecting offices.
6. Expand from a single-unit tandem system into a multiunit tandem system.
7. Deload the tandem system of traffic that can be handled more economically by other methods.
8. Maintain the most effective trunking methods under the changing conditions.
9. Improve service conditions.
10. Make the most effective use of the types of tandem equipment available.

This paper reviews the basic principles involved in the design of a dial tandem system and traces the development of the Los Angeles metropolitan area interexchange trunking problem. It describes the major elements of the present multiunit tandem system and the function it performs. Reference to minor subtandem switching points and an extensive direct trunking network is avoided deliberately for brevity. The aim is to present interexchange trunking in a growing metropolitan area as a continuing problem driven by service demand and changing technique. Highly flexible facilities are required in order to maintain an economically balanced plant arrangement and satisfy service requirements.

General Background

The serving area of the Los Angeles tandem network now comprises the Los Angeles metropolitan area proper plus

Figure 1. The Los Angeles metropolitan area

additional points described later. The term "Los Angeles Metropolitan Area" has been employed to include Los Angeles and surrounding communities, as shown in Figure 1. The Los Angeles exchange, which is the central core of the area, serves over 800,000 stations in 14 district areas. The development of these district areas varies from 26,000 to more than 132,000 stations. Three of the district areas are subdivided and each employs two central offices that are geographically separated. Other district areas are served entirely from a single central office. The surrounding exchanges each contain from one to five central offices. Within the 35 telephone exchanges involved, there are four manual-type central offices and 75 dial offices that serve approximately 1,600,000 telephones in eight toll center areas. This may be termed the primary serving area of the tandem system.

As in most metropolitan areas, the growth and complexity of the telephone system in the Los Angeles area has followed the industrial and residential development of the communities which comprise it. In the early period, say prior to 1919, the various communities were for the most part separate and distinguishable entities with a relatively light density of population and relatively small community of interest, resulting in a volume of telephone calling which could be handled economically by simple methods. As the area grew, however, under the stimulus applied by the mass influx of population following World War I, and continuing with but slight periods of slackening up to and including the present time, the situation rapidly became more complex. Starting with Los Angeles proper as a center, communities expanded in such fashion as to present in many cases a solid expanse of urban development, with no visible sign to mark the boundary between one community or municipality and the next. Along with this, of course, the population density increased manyfold.

The growth in number of people alone would have produced a volume of telephone calling of such proportions as to have called for a revolution in the manner of handling, even if no change had occurred in other elements affecting the usage of service. But there were other elements operative, so that the increase in the volume of calling was at a rate considerably in excess of linear with re-

Figure 2. The development of interexchange service

spect both to population and telephone station gain. These elements are several, but perhaps one of the most significant is the almost universal use of the private automobile for passenger transportation. The effect of this has been to soften the limitations of distance on many of the activities within the area, with the result, for example, that industry has been afforded a wider latitude than otherwise in the choice of plant locations, with the assurance that workers may be drawn from a radius limited only by their willingness to travel. As a consequence, industrial activity is widely dispersed throughout the area and, for the same reason, social interests are not limited to the immediate neighborhood of an individual, but may and do extend clear across the area.

The effect of these tendencies on telephone calling has been to increase materially the volume of calls, both business and social, over the longer distances. This effect has been heightened greatly by improvements in the art of telephony which have added immeasurably to the satisfactory quality of telephone communication.

Prior to 1919, interexchange telephone switching was almost exclusively on a manual basis, and calls between exchanges were handled as toll calls through manual toll switchboards interconnected by suitable toll or trunk circuits. With the increase in the volume of calls, however, as the result of the tendencies previously noted, the earlier methods of handling became cumbersome and costly. A significant milestone in the succession of steps taken to solve the problem was the establishment in Los Angeles of the first large scale dial tandem in 1926. Since that time, additional steps have been taken to keep pace with the growing problem and the result is the complex network of circuits and switching arrangements that is in use today.

While not of particular significance as an element affecting the problem at hand, it is of interest to note that the telephone service in the area is provided, each in its own territory comprising a part of the metropolitan area, by four companies, which are: the Pacific Telephone and Telegraph Company, a part of the Bell Telephone System; the Associated Telephone Company, Limited; the California Water and Telephone Company; and Sunland-Tujunga Telephone Company.

In addition to the primary serving area as described, a secondary area comprised of 12 Orange County exchanges is served by the Los Angeles tandem system through interconnecting trunks to and from a small tandem office in Anaheim.

Incoming traffic only is handled from more distant toll centers at Bakersfield, Pomona, San Bernardino, and San Diego. Bakersfield and San Diego, which are located 112 miles to the north and 126 miles to the south, respectively, are the most remote points having access to the tandem facilities for inward traffic to the Los Angeles area.

The traffic to and from points outside the metropolitan area is increasing to such volume that consideration is being given to handling it through a more comprehensive intertoll dial tandem which is being planned for the future. With such an arrangement in the long term picture, the ultimate scope of the metropolitan area tandem network may be restricted to what was described as the primary serving area.

Until automatic ticketing was introduced for interexchange service, all calls handled over the tandem system were operator-dialed by either the "A" operator or by the toll operator. With automatic ticketing, the subscriber is permitted to dial directly all points within the metropolitan area, except for six. Three of these are manual exchanges, and three are dial exchanges not yet arranged for using the universal numbering system. Operator-dialed calls may be directed to all points within the terminating scope of the tandem system.

Traffic is generated within the serving areas of 61 switchboards, 15 automatic ticketing offices, five attended pay stations, and the Orange County tandem office. Each originating unit has access to one or more tandem offices, plus direct trunk groups when justifiable.

Tandem development may be traced to the growing volume of metropolitan area interexchange traffic which is shown graphically in Figure 2. A comparison of traffic increase with respect to station gain may be made by referring to Figure 3. Only a part of the total traffic now is of the type handled over the tandem system as the introduction of the extended class of service, beginning in 1934, permitted calls between nearby exchanges within certain mileage limits to be handled as local calls. This in effect placed a portion of the interexchange traffic on a "free" basis to extended service subscribers.

Direct dialing by these subscribers over cross-boundary cable routes thus absorbed part of the growth that would have otherwise taken place in the type of calls handled by the tandem system. A very small amount of this traffic remains in tandem routes where cross-boundary dialing is not available and operator dialing is substituted. The remaining

portion of the calls are of the type that were all originally classed as short haul toll if placed with the toll operator or "A" board toll if placed with the "O" operator, but now with extended service, a billing schedule of exchange message unit charges has replaced the earlier system of short haul toll charges. "Person to person" or "reverse charge" calls are still classed as toll calls, as are calls involving points beyond the metropolitan area. The kind of traffic handled over the tandem system is therefore practically all of the type that involves a charge in excess of the monthly rate schedule.

Trunking Methods

In the selection of a method for trunking between telephone exchanges within a metropolitan area, there are a number of basic relationships to consider. A heavy volume of calls over any trunk group, for example, will mean that a larger number of calls per trunk can be carried. Conversely, a low volume of calls will result in fewer calls per trunk as shown in Figure 4. As the length of a circuit is increased, the requirements as to size of wire grow progressively more severe. At the same time the terminal equipment becomes more complex and expensive in order to cope with such factors as pulsing, transmission, or supervision. The cost penalties of inefficiency will therefore increase very rapidly as the mileage is extended, unless something can be done to obtain a relatively high volume of calls over each trunk group.

Another element, which is of considerable importance from an operating standpoint, is the effect of the trunking system on switchboard operation. High speed methods are particularly important where large call volume develops. Delay resulting from intermediate manual switching methods may be reduced with automatic dial switching. The number of small trunk groups an operator must search over may be reduced by tandem trunking. It also is desirable to prevent operators' tandem trunk groups from becoming excessively large because the time required to find an idle trunk may adversely affect operation during busy periods. Other factors more directly associated with design details have to be considered also, but the main underlying problem of selecting a trunking method involves a search for greater trunking efficiency, a shorter cable route, or a better method of operation. The various arrangements ordinarily adaptable to the problem are outlined in the following.

Direct Trunking

Direct trunking, as the name implies, requires an individual group of trunks between each pair of offices to be used for the sole purpose of trunking from one office to the other. If direct trunks were used exclusively, $n(n\text{-}1)$ groups of 1-way trunks would be required to interconnect n telephone offices as shown in Figure 5(A). Obviously, the exclusive use of direct trunking would result in an unreasonably large number of very small trunk groups and would introduce plant inefficiencies as well as operating difficulties.

There are advantages in direct trunking, however, that can not be overlooked. The direct route will in many cases be substantially shorter and require less complex equipment arrangements. The design need only be adequate for a specific function, whereas the design of a multipurpose routing must be governed by the most severe operating condition. With a fairly high volume of traffic, both efficient operation and the benefit of a short simple routing may be obtained. It should be noted that growth will produce an increasing volume of calls and the long term trend, therefore, is toward direct trunking.

Tandem Trunking

Tandem operation overcomes to a large extent the disadvantages of direct trunking through the use of strategically centered auxiliary switching equipment which is referred to as a tandem office. When each originating office is provided with tandem trunks, calls may be directed via tandem for completion to any point within its terminating scope. This permits the trunk groups, to and from the tandem, to be relatively large and operate at a much higher efficiency than is ordinarily obtainable with individual trunk groups. A small number of efficient trunk groups can thereby be employed in place of a large number of inefficient groups. This is demonstrated by a comparison between Figures 5(A) and (B) which have been simplified by assuming 1-way trunk groups and only eight offices. By referring to Figure 6, the effect of tandem operation and the benefit of larger trunk groups upon average trunk efficiency should be obvious.

There are disadvantages to dial tandem trunking that should be recognized in order that over-all plans may be shaped to overcome them. For one thing, the tandem office is an extra central office unit located at the hub of a large and very important trunking network. As such it becomes a sort of nerve center for the entire serving area, and nearly anything that happens within that area may affect tandem operation. A shift in the predicted pattern of growth, central office prefix changes, new central offices, new operating centers, new trunk routes, and equipment changes are some of the things that require co-ordinated activity in the tandem office. Also, from an economic standpoint, the cost of the tandem switching equipment is an item offsetting at least a portion of the increased trunk efficiency obtained. As pointed out earlier, the long term trend favors direct trunking, and this means that the economic gain obtained by tandem operation may gradually slip away, and for the heavier routings, direct trunking may become more desirable than tandem operation. A continuing study of the resulting

Figure 3. Station development in the Los Angeles metropolitan area

Figure 4. Average load carried in calls per trunk in a trunk group

Figure 6. Efficiency of a trunk group

problem is required if a balanced plant design is to be maintained.

Direct Trunking with Tandem Alternate Routing

Direct trunking with tandem alternate routing exploits some rather obvious relationships concerning the distribution of traffic between the individual trunks in a group. If traffic is offered, for example, to a group of ten trunks in an orderly manner, the first choice trunk will have an opportunity to handle all calls. The second choice trunk will have an opportunity to handle all calls except those that found the first choice trunk idle and so on to the last choice trunk. By plotting the resulting distribution of traffic, as in Figure 7, the load carried by each trunk can be observed. In this particular case, more than half the traffic is carried by the first three trunks and they are therefore quite efficient as direct trunks. In larger groups the effect is even more pronounced. The latter choice trunks are progressively less effective on a direct routing basis and a very substantial gain is realized when this traffic is mixed with similar overflow traffic in a large common tandem routing. Direct trunks may be selected so that the least efficient direct trunk carries as much or more traffic than the average tandem trunk, or an economic selection of the load to be carried by the least efficient direct trunk can be made by applying the trunk cost ratio. If, for example, the cost for a direct routing is half as much as for a tandem routing, economic balance is obtained when the least efficient direct trunk carries half as much traffic as the average tandem trunk.

There are a great many factors to consider in the practical application of alternate routing systems which involve consideration of the volume and characteristics of traffic and various other engineering or administrative problems. It is clear, however, that direct trunking with tandem alternate routing is an increasingly important element in metropolitan area plant design. This is to be expected since the advantages of both tandem and direct trunking are thus obtained.

Equipment Available for Dial Tandem Operation

There are three types of equipment that are suitable for dial tandem operation in southern California and features are available in each that provide unique solutions to distinctly different problems. Since the general function of each is equivalent and this fact may obscure the logic of appropriate selection, the relative value of the various features in particular combinations is a subject requiring considerable study. An analysis of the apparent design philosophy can lead to better understanding of the practical applications. The three types of equipment applicable are:

1. Exchange step-by-step equipment.
2. Toll and intertoll step-by-step equipment.
3. Crossbar tandem equipment.

Exchange Type Step-by-Step Equipment

Exchange type step-by-step selector equipment is designed primarily to perform the job of switching intraexchange service calls over relatively short distances. The range has been extended and operation over a much larger area has been made possible through the development of long range pulse correcting repeaters and composite signaling equipment, which have extended the limits imposed by the fact that the switches are operated directly from the impulses of the subscriber's or operator's dial.

In applying exchange type step-by-step equipment to tandem switching,

connections are established via completing trunks into the exchange service switch train of the called party's telephone office. Tandem traffic thus mixes with local intraexchange traffic and shares the common local or exchange type facilities in the terminating central office. Interexchange traffic may thereby be economically handled over local switching facilities when the dialing range is increased through appropriate use of pulse repeaters and/or larger gauge cable pairs. Actually, a sizable amount of interexchange traffic may trunk over distances no greater than the longest intraexchange connections in a large exchange, such as Los Angeles. Thus, barring other limitations, it is possible to approach the problem of designing a metropolitan area tandem system on the basis of merely increasing the range of exchange type facilities.

Transmission limitations also have been extended by improvements in telephone sets and cable facilities, but with advancing standards it is not possible to provide an acceptable talking path over as great a distance as the dialing range will permit unless additional gain is introduced. When gain is provided through use of voice frequency repeaters, the full benefit can not be obtained without furnishing more complex circuits in all connecting facilities to control transmission and permit a proper circuit termination. Exchange plant design, therefore, can not be extended beyond certain limits merely by introducing special equipment on the long trunks since it becomes necessary to redesign the connecting circuits as well.

Figure 7. Load in calls carried by each trunk

Erlang "B" basis, 148 equivalent hundred call seconds offered, 180 seconds holding time assumed

Obviously, the latter would bring penalties which would defeat the purpose of designing a tandem system with exchange type plant facilities.

There are a number of ways of dealing with this kind of problem and most of these have been employed in the Los Angeles area. One of these is to narrow the terminating scope of the tandem for a particular originating point so that the transmission requirements are less severe and by this sacrifice reducing the requirements for transmission gain.

Another method employs dialed-in vacuum-tube repeaters in the tandem office which operate selectively for particular routings that require a small amount of additional gain. Since a larger variety of repeater balance conditions are presented maximum gain can not be maintained. As a result, it is either not suitable for as distant an originating point or some part of the terminating area may remain beyond limits.

A third method may employ two grades of trunk groups; namely, a low grade group for calls terminating within a restricted zone and a high grade group for calls switched between outlying points. Various combinations of the preceding also are applicable, but it should be recognized that since we are approaching the problem from the standpoint of extending the range of exchange type plant the inherent limitations remain. Under these circumstances, marginal conditions are continually encountered in expanding the dialing area and a general solution can not be obtained without considering a different approach to tandem plant design.

The problem previously discussed can obviously be eliminated if the design of a tandem system is approached from the standpoint of extending the application of toll-type plant. Interconnections between remotely located subscribers are fundamental to long distance service and the toll plant must therefore provide features to overcome the resulting obstacles.

Toll and Intertoll Type Step-by-Step Equipment

The local service terminating selector path in a step-by-step dial office is paralleled by a toll train consisting of selector and connector switches of more elaborate construction. The apparatus and circuits provided overcome the limitations of the local train by furnishing features for matching line and trunk impedance, plus visual operators' signals and a higher grade battery feed circuit of the 48-volt repeating-coil type.

A tandem office also can be designed with toll-type selector switches and when associated with even more highly refined intertoll dialing facilities transmission can be effectively controlled and other important toll features retained. Transmission control in such cases is accomplished by the use of pads in the toll trunks which are cut out on via connections with other toll trunks or remain in on the shorter routings to reduce unnecessary gain and make it possible to maintain voice repeater balance.

Intertoll selector switches are arranged to pulse directly from a simplex or composite leg, thus eliminating needless conversions from composite dialing to loop dialing and the attendant pulse distortion. As a result, the use of pulse correcting repeaters is avoided, which tends to offset the excess cost of the more elaborate equipment.

The associated equipment arrangements provide a better impedance match between the toll switching trunks and toll circuit, and permit dual use of the toll switching trunk for inward operator routed calls and intertoll dial tandem calls. Two-way operation is possible on the toll circuits.

Thus, step-by-step tandem facilities may be provided for extending either the exchange switch train or the toll switch train. The application depends upon the types of traffic, the relative volume and the geographical development of the area. In the Southern California area both types are employed; however, the Los Angeles metropolitan area system employs the exchange type plant since the character of the traffic and the distances involved more nearly coincide with exchange trunking requirements. A relatively small amount of traffic is handled that eventually will be shifted into toll plant arrangements.

It should be apparent that there are many other factors to consider in the design of a tandem system. Step-by-step tandem equipment without senders, directors or equivalent has limitations that make consideration of other arrangements desirable. With the development of the crossbar tandem system ideal solutions have been provided for many of the problems encountered with step-by-step plant.

Crossbar Tandem Equipment

To facilitate discussion, it would be

well to have in mind at this stage the fundamental difference between the step-by-step and crossbar tandem systems, as employed in the Los Angeles area. In the step-by-step tandem system, the movement of the switches is controlled directly by the impulses from a dial or sender in the originating office, and connections are established through fixed paths determined by the equipment arrangement as installed. Since the impulses are absorbed in switch operation and are not stored, they are not available for any purpose should, for any reason, the first attempt at establishing a connection fail.

The crossbar tandem system, on the contrary, is what may be designated as a common control system. Instead of actuating the switches directly from the impulses, these impulses are recorded in a control circuit, which in turn determines the switch operation necessary. The common control idea is not really new except for its method of application, for manual switching is a form of common control operation. Here the operator receives the desired number from the calling subscriber and, by means of the switchboard cord circuits and jacks, sets up the connection. If trouble is encountered or if the trunks are all busy, the operator can make a second trial or select another routing. An equipment or cable failure may be detected and reported while the subscriber remains utterly unaware of the difficulties experienced in establishing the telephone connection.

In the crossbar tandem system, relays and switches perform the operating function instead of a human operator. After receiving the called number the control equipment proceeds to determine if the first choice path is available and if so, sets up the proper switches; if not, other paths may be tried.

Crossbar tandem equipment may operate into either the step-by-step local train, the toll train or both. Appropriate selections between two or more completing paths can be controlled automatically by indications received from the incoming trunk group. Various other features unique to the common control system are covered in the detailed description of the crossbar tandem system. Equivalent treatment has been given elsewhere to step-by-step equipment and other related elements of telephone plant. The references given at the end of this paper should therefore be noted for more complete sources of information on these subjects. It is suggested, however, that correlated understanding will be facilitated if attention is focused particularly on features affecting trunking flexibility and service protection.

Flexibility

First, let us consider trunking flexibility. With a step-by-step tandem office where a large number of equipment items are assembled at the time of installation in various groups and cross-connected in accordance with a predetermined plan, the exact arrangement is the result of a predicted pattern of development which antedates the maturity of the forecast by roughly three years. This three years includes the normal intervals of six months for the average age of basic development and traffic data, about 18 months for engineering, manufacturing, installation, and testing, and another year from the in-service date to the time that predicted growth will require a subsequent addition for further relief. Even though mass requirements may be predicted quite accurately, excess capacity in one path through a switch train is of no value if an overload develops in another, since routings through the tandem office are controlled directly by the digits received.

The equipment, being assembled into a relatively rigid pattern by what amounts to a phase of manufacturing performed at the customer's premises, can not be readily rearranged except through another construction cycle. Since the trunk and pulse repeater requirements involve the use of a number of different circuit arrangements for matching complementary facilities, minor readjustments frequently require additional apparatus. The normal time required for changes is therefore the controlling element when thinking of flexibility, since maintenance of a proper balance in the system demands the ability to foresee changing conditions sufficiently in advance to satisfy the limitations of construction intervals. From the standpoint of flexibility the application of step-by-step equipment in tandem operation is therefore most favorable when conditions are stable.

In contrast to step-by-step operation the digits dialed into a crossbar tandem do not control the selection of a path through the equipment. The theory of operation is not at all similar and the trunking pattern within the tandem office is fixed by the size of the unit and the paths through the equipment are independent of the digits dialed. Furthermore, only one type of incoming trunk circuit is required for loop dial pulsing and another for composite dialing. The loop dial trunks are also usable for composite dialing when pulse converter circuits are available. In the general case, for this area, outgoing trunk circuits are employed only when a conversion from loop to composite signaling is required. Thus, any change in routing or in individual trunk requirements can usually be handled in crossbar tandem on a routine basis merely by issuing instructions to the maintenance forces.

Adjustments can be made easily in a matter of hours that normally require an extensive construction interval with step-by-step equipment. With only a reasonable anticipation of the kind of situations most likely to be encountered the problem of flexibility is limited only by the maximum call carrying capacity of the unit. The increased flexibility of the crossbar tandem equipment tends to minimize the effect of unforeseeable variations in traffic and provides an important tool for managing the trunk plant. The problem that remains is therefore largely one of predicting the mass requirements.

It should be clear that a large percentage of the total traffic is stable while a lesser part is expected to be more volatile. So if a plan can be developed under which highly flexible facilities are used for the less predictable items of traffic with the more stable items going over the less flexible arrangements, important advantages of both types of plant are utilized. Other points to consider are the number of switching combinations required and the total volume of traffic. Obviously, with only a few switching combinations, where the traffic is divided over a small number of paths or with a relatively low volume of calls, the limited flexibility of step-by-step equipment may be adequate for the conditions encountered. The two systems are not competitive in this respect since each can fulfill the requirements of different circumstances or one may support the other.

Service Protection

The question of service protection can be studied from various angles. Performance statistics may be examined or construction details compared, but a more basic approach should augment such observations. This requires an evaluation of the characteristic differences in the way the two systems operate. For example, with step-by-step equipment the relatively simple circuits respond to battery and ground or their absence, and mechanically follow dial pulses or supervisory signals. Many base metal contacts are used, and because of the sliding action and consequent wear in the switches the maintenance function is organized around the application of system-

atic preventive measures. Periodic cycles of testing, cleaning, lubricating, replacing of worn parts, and adjusting by skilled craftsmen keep the equipment in the best possible working condition.

With crossbar equipment, however, a further step has been taken. The switch employs a relay contact spring type of action, and uses precious metal contacts in voice circuits, permitting quieter connections and eliminating the bulk of manual labor required in searching for potential breakdowns. An even more significant point is the use of special circuits to monitor critical functions and check for proper operation before a call is established. When a failure is detected duplicate circuit elements and retrial features become operative. Further refinement is obtained with automatic testing and monitoring facilities permanently established in the test center, to record troubles and aid the maintenance force in isolating and correcting them. Thus, from a service protection standpoint, there is considerable assurance that crossbar tandem equipment offers advantages that will be of increasing importance in the advancing of future standards of service.

Dial Tandem Network

In the Los Angeles metropolitan area, five tandem offices, as described in the following, are utilized to provide switching facilities for trunking between the various exchanges of the area. Two of the tandem offices are located in Mutual Building which is the wire center for the area. The other three tandem offices are strategically located to provide coverage for particular sectors of the area.

Los Angeles Mutual Step-by-Step Tandem

This unit which is usually referred to as the "long haul tandem" was first placed in service in 1926.[2] Many changes and additions have been required since that time to keep pace with the development of the area, but basically the unit performs the function it was originally designed to accomplish. The present plan employs the following major equipment items:

7,697 selector switches
92 rotary out trunk secondary switch units
3,571 pulse repeaters (20 types)
80 voice frequency repeaters
740 composite sets (7 types)

The voice frequency repeaters are employed on a "dialed in" basis and their use can be controlled by operator's routing instructions that direct the use of a preliminary digit "0" where additional gain is required.

The general transmission plan for this tandem is symmetrical, and Los Angeles exchange connections are limited to a circuit loss between the subscriber and the tandem of 5 decibels for either originating or terminating. The first fringe offices are limited to 6 decibels and those beyond the first fringe are limited to a 7 decibel loss. Thus the over-all service may be established between subscribers in the various exchanges in accordance with the following:

Typical Types of Connections	Transmission Limit, Decibels
Los Angeles to first fringe exchanges	11
Los Angeles to outer exchanges	12
Between fringe exchanges	12
Fringe to outer exchanges	13
Between outer exchanges	14

In addition to the outer exchanges within the metropolitan area this unit connects with the Orange County tandem to serve the following exchanges:

Anaheim	Laguna Beach
Brea	Newport Beach
Buena Park	Orange
Fullerton	Placentia
Garden Grove	Santa Ana
Huntington Beach	Westminster

These exchanges also may reach the Los Angeles exchange and certain others through their operating centers which may dial through the Orange County tandem into the Mutual step-by-step (long haul) tandem.

Incoming trunks are provided for the more distant points; namely, Bakersfield, Pomona, San Bernardino, and San Diego as mentioned previously.

The traffic capacity of this unit is approximately 39,000 calls during the busy hour assuming an average of about three minutes per call. These calls originate over approximately 2,650 incoming tandem trunks.

Since 1926, this tandem unit has been the main switching center for all operator-dialed and automatic ticketing traffic. It is the only unit with complete access to the entire metropolitan area and Orange County points. Experience with the more recently introduced crossbar tandem at Mutual office indicates advantages in ultimately reducing the scope of the step-by-step unit and expanding the coverage of the crossbar unit. This would make the crossbar tandem the main switching center and ultimately reduce the step-by-step unit to the role of a short haul tandem or sector tandem.

Los Angeles Mutual Crossbar Tandem

At present this unit is referred to as the "short haul tandem." It was first placed in service in January 1948 and immediately took over the function of a small step-by-step short haul tandem previously employed for handling traffic between the Los Angeles exchange and Pasadena, Glendale, Beverly Hills, and Culver City. Additional capacity was provided to permit expansion of the area of coverage to include all points within a range of approximately 2,000 ohms trunk resistance. This limited the total scope roughly to Los Angeles and contiguous exchanges.

The reasons for initially limiting the coverage of the crossbar tandem were largely for purposes of expediting the installation. To obtain complete coverage, additional development work would have been required to provide features corresponding to the step-by-step tandem "dialed in" vacuum tube repeater arrangements and to receive more than seven digits or outpulse more than six digits. Since the use of "dialed in" repeaters is gradually being eliminated and a numbering plan has been selected that will not require more than seven digits, the delay and expense associated with the required development work could not be justified to care for what appeared to be a temporary condition.

Progress has been made in expanding the coverage with the crossbar tandem and under the latest plan all dial exchanges within the metropolitan area except two requiring eight digit dialing will be served by completing trunks. The originating side will be expanded as conditions permit until complete coverage of the metropolitan area is obtained.

A full unit of crossbar tandem equipment was installed initially with a capacity of about 28,000 busy hour calls. The quantities of major equipment items are as follows:

2,200 incoming repeated supervision trunk circuits
20 trunk link frames
20 office link frames (with extension frames)
160 dial pulse senders
8 markers

The transmission plan for the Mutual crossbar tandem is identical to the Mutual step-by-step tandem.

Los Angeles Lafayette Sector Step-by-Step Tandem

The Lafayette sector tandem is located in Huntington Park approximately six miles south of Mutual office and is along the route from Los Angeles to such points as Long Beach, Downey, and Compton.

It was first cut into service in May 1949 and has capacity for about 10,000 busy hour calls.

The main purpose behind the sector tandem idea is to eliminate back-haul of traffic and thus permit shorter routes and finer gauge trunk cables. The scope of coverage is limited and in this case includes the central, southerly, and easterly districts of the Los Angeles exchange and outlying points. More specifically the area is as follows:

Los Angeles Exchange

Adams District	Mutual District
Angelus District	Republic District
Axminster District	Richmond District
Drexel District	Thornwall District
Lafayette District	

Other Exchanges

Compton	San Pedro
Downey	Wilmington
Long Beach	

Facilities are provided for 724 incoming trunks and 928 outgoing trunks requiring major equipment items as follows:

1,671 selector switches
20 rotary out trunk secondary units
1,122 pulse repeaters

The transmission design of this and all other sector tandems is limited to 6 decibels inward plus 6 decibels outward. An over-all loss between subscribers of no more than 12 decibels is therefore obtained.

Los Angeles Thornwall Crossbar Sector Tandem

The Thornwall sector tandem is located roughly six miles south of Mutual office and about four miles west of Lafayette. It was first cut into service in November 1949 with a capacity for about 10,000 busy hour calls.

The Thornwall office is along the route from Redondo Beach and Inglewood to central office districts in the central, southerly, and westerly part of the Los Angeles exchange. The following points are within its serving area:

Los Angeles Exchange

Adams District	Republic District
Axminster District	Richmond District
Drexel District	Thornwall District
Lafayette District	Whitney District
Mutual District	

Other Exchanges

Compton	Redondo
Culver City	El Segundo
Hawthorne	Lomita
Inglewood	Torrance

The following major equipment items have been provided for the Thornwall tandem:

1,200 repeated supervision trunk circuits
10 trunk link frames
10 office link frames
54 senders
5 markers

Los Angeles Hollywood Sector Crossbar Tandem

The Hollywood sector tandem was first cut into service in February 1950. It is located 6.7 miles northwest of Mutual office and is along the main route to San Fernando Valley points. It serves exchanges in the sector to the north and west of Mutual office as follows:

Los Angeles Exchange

Axminster District	Republic District
Drexel District	Richmond District
Hollywood District	Whitney District
Mutual District	
Olympia District	

Other Exchanges

Beverly Hills	North Hollywood
Burbank	Reseda
Canoga Park	San Fernando
Crescenta	Santa Monica
Culver City	Van Nuys
Glendale	West Los Angeles

Nearly a full unit of crossbar tandem equipment was installed initially with a capacity for 25,000 busy hour calls. The following major equipment items were provided:

2,160 repeated supervision trunk circuits
18 trunk link frames
18 office link frames (with extension frames)
130 dial pulse senders
8 markers

Summary

Dial tandem facilities are employed in the Los Angeles metropolitan area to permit rapid and economical interexchange telephone service over the wide area of subscriber community of interest. The five major tandem offices are part of an over-all system designed primarily to:

1. Provide operating methods that will permit the handling of calls at a speed comparable to a local grade of service.

2. Permit high trunk efficiency and an economically balanced plant design that is consistent with advanced telephone practice.

3. Allow a less exacting plant design than would be required if toll long-distance type facilities were employed, so that the large volume of calls may be handled at minimum cost to the customer.

Two fundamentally different types of equipment are employed and each contributes important advantages in this area. The step-by-step tandem equipment, which is of the same type employed in the local dial offices and around which the dial tandem network has grown since 1926, is best adapted to stable conditions or small units. The more recently developed crossbar tandem with its highly flexible trunking arrangements is a valuable tool for meeting the requirements of the most volatile service demands. It also includes features which extend the idea of service protection beyond reliance upon high grade preventive maintenance to include the conception of self checking and prompt completion of calls even under many trouble conditions.

While long-term growth tends to increase the effectiveness of direct trunking methods over tandem trunking, other adverse trends are constantly causing additional segregations in the traffic. As the result, the effectiveness of interexchange trunking methods remains dependent upon the tandem switching system.

No Discussion

The Universal Director in Strowger Automatic Telephone Systems

J. E. OSTLINE
FELLOW AIEE

FOR more than half a century the Strowger Automatic, or "step-by-step" switching system has been well known to telephone engineers and telephone operating administrations throughout the entire world. Its inherent simplicity, flexibility, and stability in operation have made it suitable for telephone communication requirements in the smallest exchanges as well as the largest metropolitan areas.

The Strowger Automatic switching system, as commonly used, is a "direct" dial controlled system in that each connection is extended on a decimal number basis, stage by stage, by electromechanisms that are under the direct control of the dial at the calling station. This eliminates the need for common controls or registers and thereby offers maximum simplicity and a minimum amount of equipment for a given exchange.

The step-by-step method of operation inherently associates the numbering plan with the switching stages required to establish a connection. In single exchange units up to 10,000 terminals or in small multioffice networks this does not introduce any difficult problems from either a numbering or trunking viewpoint. However, when large multioffice city exchanges or metropolitan multiexchange networks are involved, the direct dial control method is apt to prove somewhat inflexible and sometimes costly. This is particularly true when conditions favor the use of existing tandem trunking routes in a conversion from manual to automatic operation or in a program of interexchange trunking additions or readjustments to meet expanding area requirements.

The problem of providing economical and flexible interexchange trunking with universal numbering, while yet retaining the desirable features inherent in Strowger step-by-step equipment and operation, was met nearly 30 years ago when Automatic Electric Company designed and made available the Strowger Automatic Director. This unit of equipment first was used to meet several complicated interoffice trunking problems in the Havana, Cuba, exchange network in 1924. A year earlier, it had been officially adopted by the British Post Office for the conversion of the telephone network of the London Metropolitan Area from manual to automatic operation.[1] In this network the problem of interoffice trunking was rather complicated due to the fact that the metropolitan telephone network had been built up from a number of isolated manual exchange areas which were consolidated when the British Government assumed ownership of the country's telephone communication systems.

That the Director in conjunction with the basic Strowger Automatic equipment has proved practical and economical is indicated by the fact that Strowger Director operation has since become standard for all metropolitan area telephone networks in Great Britain.

Further Director Developments

The London Director was originally designed to provide only interoffice and tandem trunking controls with universal numbering. It soon became apparent, however, that the Director could be arranged to provide many additional types of services and facilities in Strowger Automatic switching operations. Some of the facilities or controls considered for future use were:

a. Common trunking controls.

b. Alternate routing.

c. Class of service discrimination.

d. Subscriber-dialed short-haul (*AB*) toll service controls with automatic call recording.

e. Operator key-dialed long-distance service controls with semiautomatic call recording (national toll dialing).

Directors containing one or more of the foregoing or any other controls, in addition to the original trunking control functions, now are referred to as Universal Directors.

About 1938, Bell and independent companies providing telephone service in the Los Angeles, Calif., metropolitan area began to consider the possibility of providing subscriber dialing in place of manual operation for short-haul toll calls between the various exchange areas in this network. At this time Automatic Electric Company had already provided a Director-controlled toll dialing and automatic call recording system for the Belgian Telephone Administration. They, therefore, proposed to the independent operating telephone companies in the Los Angeles metropolitan area a Director arranged not only to provide trunking controls for interexchange traffic, but also to control subscriber dialing and automatic call recording for short-haul toll traffic as well as to provide controls for other facilities and services suitable for the area.

After various plans for Director operation had been submitted to and studied by the various companies concerned, the Associated Telephone Company, Ltd., Santa Monica, in 1944 installed and placed in operation a "pilot" installation of Director-controlled automatic short-haul toll ticketing which provided direct

Paper 50-169, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing May 11, 1950.

J. E. Ostline is with the Automatic Electric Company, Chicago, Ill.

The author wishes to thank Dr. Arthur Bessey Smith, Mr. C. F. Ffolliott, and other staff members of Automatic Electric Company for their suggestions and assistance in preparing this paper.

Figure 1. Los Angeles metropolitan extended area

The letters "O.A." mean "Office Assignments"

dialing access to a majority of exchanges in the Los Angeles metropolitan area. This installation clearly indicated the many advantages of Director trunking control and "automatic toll ticketing" facilities. This automatic toll ticketing facility now is referred to as the Strowger Automatic Toll Ticketing (*SATT*) system.[3]

As a result of the experience obtained from the Santa Monica pilot installation, the several independent operating companies in the Los Angeles area now have formulated plans to convert to Universal Director operation. One such installation with automatic *AB* toll ticketing and several other facilities recently has been completed for the Sunland-Tujunga Telephone Company, at Sunland, Calif. The Universal Director provided for this installation is described in outline in this paper.

The Universal Director

Facilities

The Director equipment described herein has been designed to provide facilities to meet the various operating requirements encountered in the Los Angeles metropolitan area, Figure 1, which now contains over 1,250,000 stations. Controls for the following facilities are provided:

a. Mixed 6-digit and 7-digit numbering.

b. Director release on local exchange calls.

c. Interexchange trunking with common translators.

d. Secondary trunking.

e. Alternate routing.

f. Class of service discrimination.

g. Line testing.

h. Station identification on party lines.

i. Automatic short-haul toll ticketing (*SATT* system).

j. Emergency directive.

Outline of Director Equipment

The Director and associated equipment is made up of standard Strowger components such as rotary and 2-motion switches and various types of relays. These various units are arranged so as to provide the same easy maintenance facilities which have always been inherently characteristic of all Strowger switching equipment.

In the original (London) Director the translation control was built into each Director. In the Universal Director this facility is provided in a common control unit termed the Translator.

When automatic toll ticketing service is provided in an exchange, several other units of equipment are required besides the Director, as indicated in Figure 2. The detector and dater-timer are units common to the *SATT* operation. Ticketers, tabulators, and associated tape perforators are provided on the basis of short-haul toll traffic.

Outline of Facilities

Mixed Digit Numbering. The Los Angeles area numbering plan will eventually be of the so-called "2 by 5" 7-pull type. At the present time, however, a mixed 6-pull and 7-pull numbering is used. The Director therefore is arranged so that trunking and service controls can be established from dialing 6-pull or 7-pull numbers as well as zero and 3-digit service codes.

Director Release on Local Calls. (See Figure 3 and Appendix I.) All switching components in Director exchanges are of the normal direct-dial control Strowger type, and they can be controlled either directly from station dials or from Directors. Therefore, all Directors are provided with adjustable "strapping" facilities which enable them instantly to recognize local exchange codes. When a local code is dialed the Director releases after the code has been dialed

Figure 2. Functional arrangement of Director exchange equipment

nto it, and the call then is completed under direct control of the calling station dial.

This facility considerably reduces the number of Directors required in an exchange. Local selector ranks also are reduced because of the Director control in extending the call to the first numerical selector.

Director Trunking Controls. (See Figure 4 and Appendix II.) After a special service or exchange code has been dialed and stored in a Director, the latter is momentarily associated with a Translator common to all Directors in the exchange. The dialed code then is sent to the Translator, which instantly sends back a "directive" to the calling Director and releases itself. This directive contains the information required for the Director to extend the call to a service operator or the terminating exchange via direct or tandem trunking.

The directive produces from one to five trains of pulses of suitable numerical values. After a terminating exchange is reached, the numerical portion of the called number is transmitted in the same value as registered in the Director. After transmission is completed the Director releases.

The third digit of a called exchange code often is used in tandem trunking. When this is required, the directive does not contain this digit, but it does contain a "C" digit control which causes this digit to be resent from the original called number registration storage in the Director.

Another type of tandem trunking encountered in the Los Angeles area involves passing certain calls via tandem exchanges using crossbar type switching. This requires a search for a register in the crossbar exchange into which the required called station information can be passed. When a call of this type is encountered, the Translator passes this crossbar control along with the directive to the Director. After the directive has extended the call to the crossbar tandem exchange, this control causes the Director to wait during the search for a sender in the crossbar exchange, and when the sender is connected to the trunk, the Director retransmits the called number into it in the same value as originally dialed by the calling station. The Director then is released.

Interexchange trunking control is the facility for which the Director was originally designed.

Secondary Trunking Controls. When desired, the Director can be used to control so-called secondary trunking with 25-trunk or 50-trunk rotary switches. When used in direct-dial controlled exchanges (non-Director), this type of trunking has to be preselective due to the time limitation imposed by the interdigital period. With the Director this interdigital period can be controlled by the switch-through function which takes place in the secondary switch when a free trunk is found. This interdigital period control therefore can be used to provide post-selective secondary trunk selection with continuous hunting. This continuous hunting is limited only by the setting of the time-cut-off facility in the Director.

Class of Service Controls. This is the facility by which the Director controls access to the services to which a calling station is entitled. For instance, Class-1 stations may receive free service to a larger area than Class-2 stations. Therefore, if a Class-2 station dials into a Class-1 free area, the Director will complete the call on an AB toll basis.

The class of service control is transmitted to the Director from the primary selectors on a group basis; that is, certain groups of primary selectors all provide the same class of service. Line equipment can also be arranged to transmit this control on an individual per-line basis. This method permits changes in class of service without the need for transferring the line into another selector group.

Alternate Trunk Routing. Whenever an outgoing tandem trunk group becomes busy (*ATB*), the translator equipment receives an indication as long as this condition remains. Calls which normally would be routed via a busy trunk group are then rerouted via other tandem trunk groups by means of an alternate directive. This facility is also used to concentrate special service trunks into common positions during light load periods. Ordinarily this concentration process requires individual switching of each trunk while it is in a free condition. With the alternate routing facility this change-over can be done at any time regardless of the trunk condition by the operation of one common key.

Line Testing. It is, of course, well known that in both manual and automatic switching systems a partial and sometimes a solid ground on the tip (positive) side of a station line does not seriously interfere with signaling or dialing functions. However, in automatic exchanges using the *SATT* system, ground leaks on station lines must be kept to certain minimums in order to permit correct identification of party stations.

In order to prevent stations on lines with ground leaks beyond a permissible maximum from initiating *SATT* calls on which party identification is required, the Director always tests the line by which it is seized. If a ground fault below the permissible minimum is encountered, this fact is recorded. If the dialed exchange

Figure 3. Director release on local call (see Appendix I for circuit explanation)

code and class of service indicates a free call, the Director permits completion of the call in the usual manner. If the dialed code indicates an *AB* toll call, the Director cancels the automatic completion of the call and extends the calling station to a manual operator over a special trunk group. The operator then can complete the *AB* toll call. The call coming in over the special trunk group is an indication of the line fault, which the operator will report to the maintenance staff.

Party Station Identification. In order to provide *SATT* service to 2-party and 4-party stations, means must be provided to identify which particular station on a line is initiating a call. This party station identification facility is provided by means of an "identity" dial, Figure 5, at each of the stations on a party line, and "party group" recording equipment in each Director. Identity dials are ordinary automatic dials as manufactured by Automatic Electric Company with the addition of a party-identity impulse mechanism. This added facility in no way affects the normal function of the dial.

Whenever the Director is taken into use it tests for and registers party-identity pulses, if present, during the dialing of the second code digit. At the end of this digit the Director knows in which group of connector terminals the calling station is located. This party-identity registration is used only if the call is an *AB* toll call and, in such case, this identity control will indicate to the Detector the particular hundreds groups of terminals in which it must search for the calling station terminal number.

Party-identity pulses from station dials do not interfere with the regular dial pulses or the operation of the equipment which is controlled by such dial pulses.

This party-identity facility can also be used, in connection with suitable line equipments, to provide "message metering" for party-line stations.

The fact that a station is located in a particular hundreds group of terminals which serves party-line stations does not always indicate that the station has party-line service. Individual line stations may also be located in these groups to obtain correct traffic loadings throughout an exchange. An individual line station in a party-line service group must, however, be equipped with an identity dial corresponding to the particular hundreds group in which the individual station terminal is located.

Automatic AB Toll Ticketing. The primary control of *SATT* system operation is centered in the Director, see Figure 4. When a calling station dials another station located in a short-haul toll area, the dialed code will indicate this fact to the Translator. The Translator then will include with the returned directive an indication that the call is to be ticketed and also the rate which will apply to the call if completed.

As soon as the Director has the indication that the call is to be ticketed, it prepares itself to transmit "ticket data" to the Ticketer unit which is always included in a toll call trunk path. The first action in this procedure is for the Director to "call in" the Detector. When acknowledgement is received from the Detector, the Director transmits to it the particular hundreds groups in which the Detector must search for the calling station number. This indication is normally Group 1 unless the call is from a party-line station group, in which case the indication will be Group 2, 3, 4, or 5. This party indication is stored in the Director by the calling station identity dial as described previously.

As soon as the Detector has received the group indication it detects the calling

party number and transmits it to the Director for storage. At the end of this operating cycle, which requires less than one second, the Detector is released.

The Director, upon the receipt of the directive, proceeds to establish the talking path to the called station. As soon as the selector permanently associated with the Ticketer has been reached and positioned, the Director receives a signal from the Ticketer that it can proceed to "write up" the ticket data. The Director then transmits in high-speed code these items to be stored in the Ticketer: calling station number and class of service; called station number and rate applying to call; and identity number of the Director.

The transmission of these items proceeds over the "tip" side of the trunk simultaneously with the transmission of the switch positioning pulses over the "ring" side of the trunk. If the ticket-data transmission is not completed before the last positioning digit is to be transmitted, this digit is held in the Director until the ticket-data transmission is completed. When the final switch positioning digit has been transmitted the Director releases.

Emergency Directive. As described previously, the translation function for all Directors in an exchange is performed by a common translator. In order to prevent stoppage of service due to interrupted translator operation, an "emergency directive" facility is provided in each Director.

When a code has been dialed into a Director it calls for a directive from the translator. However, if due to any operating fault no directive is received back within 15 seconds, the Director will extend the call to a *D.S.A.* operator under control of the emergency directive and then release itself. The operator will then take whatever action is required according to local operating practices.

Outline of Director Operation

Station Calls. When a station initiates a call, a linefinder extends the calling line to a primary selector which is similar to a first selector in a non-Director

Figure 4. Schematic of Director components (see Appendix II for circuit explanation)

Figure 5. Identity dial

exchange. Permanently associated with each primary selector is a director-hunter rotary switch, the banks of which are wired to Directors. This hunter switch searches for a free Director and extends the calling line and the primary selector to it. On seizure, the Director first tests the calling line for ground insulation, then checks for and registers the class of service to which the calling station is entitled, and finally extends dial tone to the calling line. The calling subscriber now dials the code of the desired station or special service. As soon as this code has been dialed and stored, the Director goes into action as outlined in an earlier section if the call is local, or free to an adjacent exchange area. If call is *AB* toll, it is processed by the Director as already described.

Traffic and Fault Controls. If a Director after seizure fails to completely record a called number or correctly transmit outgoing switch positioning pulse trains, it returns a busy tone to the calling station and gives an alarm. The calling station can release, but the Director will be held busy and locked in the position in which it produced the alarm. This assists the maintenance force in locating the fault.

If the Director is seized by a "short" or "ring-grounded" line, it will, under the control of a suitable time delay device, call in a directive from the Translator which will extend the faulty line to an alarm unit via a level in the primary selector. This will free the Director for normal traffic and alert the maintenance force.

If a nonexisting code is dialed by a calling subscriber, the line is extended either to an operator or to a "no-such-number" tone via a level in the primary selector, and the Director is released.

If dialing of a number is incomplete the time-out facility extends a busy tone to the calling station from the Director, which then will release when the calling subscriber replaces the handset.

If all trunks in a Director hunter bank become busy, the hunter switch stops searching and the calling station receives a "regular" or "all-trunks-busy" tone.

Traffic Registration (Peg Counts). The Translator for each exchange and special service code is arranged to register each call attempt. Correct and detailed traffic data on all traffic routes therefore is obtained from which trunking and equipment changes and other traffic items can be accurately determined.

Each Director also is provided with traffic registers which separately show the number of local calls and the number of outgoing calls processed by each Director.

Monitoring and Test Facilities. A Director monitor panel provides visual observation of all basic Director functions during the progress of a call. "Make busy" and complete test facilities also are provided in this panel.

Conclusion

From the foregoing outline of the Universal Director it will be seen that it is not a fixed or rigid unit of equipment, but that it can be arranged to provide a multitude of service facilities and controls to suit almost every conceivable automatic switching arrangement. Dr. Arthur Bessey Smith states,[8] "We can make the complete Director assembly do whatever is necessary to direct a call to the desired distant office and to connect with the desired telephone." This we now know can be done regardless of whether the desired telephone is located in the originating exchange or in an exchange anywhere within the nation, with the aid of the Strowger Universal Director.

Figure 6 (left). A portion of two Directors

Figure 7 (right). Translator frame

Appendix I

Figure 3 is a functional diagram of an intraexchange call with FAirfax 7 used as local office code.

As depicted, a calling subscriber's line has been extended by way of its line and cut-off relays, linefinder, and primary selector through the director hunter to a Director. The Director is in a seized condition and the selector, though seized and busy, has only its *F* relay operated. Relay *A* in the Director is maintained operated by way of the line loop and subscriber's dial to ground. When the subscriber pulls the dial off normal and releases it for the first digit, relay *A* will pulse following the dial impulses and restore once for each impulse. Relay *C*, when operated, closes a circuit to the motor magnet of the sequence switch, which magnet remains operated for the duration of the digit.

The first digit of the office code, FAirfax 7, will be a 3. When this digit is complete, relay *A* in the Director will resume its operated condition and relay *C* then restores in the interdigital period. Register *1* now has its wiper standing on its fourth bank contact. The restoring of relay *C* allows the sequence switch magnet to restore and to advance its wiper onto its second bank position. On the next digit dialed by the subscriber, relay *A* will follow the dial impulses and relay *C* and the sequence switch will be maintained for the duration of the digit with register *2* taking one step for each dial impulse, which in this case is *2*. When the digit is complete, relay *C* and the sequence switch restore, and register *2* is now standing on its third bank contact. Relay *D* now operates on a circuit through the wipers of registers *1* and *2*. Upon operating, relay *D* closes a circuit from the closed contacts of relay *A* in the Director by way of resistor *R-1* to the number-1 winding of the *A* relay in the primary selector. Relay *A* in the selector operates, closing the circuit to relay *B*, and upon operating, *B* will cause relay *C* to operate and lock to ground at relay *D* in the Director by way of the director hunter.

The third digit dialed by the subscriber, in this case 7, will cause relay *A* in the Director to pulse, relay *C* and the sequence switch remaining operated for the duration of the series, and register *3* stepping in the same manner as registers *1* and *2* stepped on previous digits. However, during the third digit, each restoration of relay *A* on an impulse will open a ground circuit to the *A* relay in the primary selector. The selector *A* relay will restore and, by way of the contacts of its slow release relay *B*, send an impulse to the selector vertical magnet. The selector will take one step for each impulse from the Director *A* relay. This third digit then is impressed on register *3* and the vertical magnet of the primary selector simultaneously. When the digit is complete, relay *A* in the Director resumes its operated condition, relay *C* restores as well as the sequence switch, and a circuit is closed on the bank of register *3* to relay *E*. Relay *E* operates, opens the locking circuit for the primary selector *C* relay so that it may restore and allow the selector to do rotary hunting. Relay *E* also opens the circuit maintained between relay *H* in the Director and relay *F* in the primary selector. These two relays restore and when relay *F* restores, the subscriber's line is connected to the selector equipment in a normal step-by-step manner. Then the Director is released to other subscriber traffic.

If perchance the called office code is one which has its first two digits the same as for local office codes, but the third digit indicates an office code requiring translation and sending, the functions in the Director and primary selector would be the same up to the point where the third digit is complete. Register *3*'s position at the completion of the third digit would be on some bank contact other than *8* and relay *E* would not operate. The sequence switch, when it restores, then closes a circuit to relay *S*, which operates, and by way of contacts not shown, calls for a translation of the dialed code. Relay *S* also opens the circuit to relay *A* in the primary selector. The primary selector, though it has stepped vertically on the third digit, was not able to hunt in the rotary direction due to the fact that its *C* relay was locked to ground at relay *D* in the Director. Relay *A* in the selector restores, opening relay *B* which upon restoration actuates the selector release magnet which restores the shaft. Sending, by way of the primary selector and subsequent switches, will ensue as is normal for translated office codes.

Appendix II

Figure 4 depicts the schematic diagram of the Universal Director and associated component units involved in the registration, translation, and sending of subscriber-dialed calls to be completed on either a free or automatic toll ticketing basis, as well as local special service calls.

Pulse Path

The circuit from the *A* relay in the Director via contacts of relay *F* in the primary selector, the linefinder, line relays, subscriber's line, and instrument is the in-pulse path. All digits dialed to the Director by the subscriber will be "in pulses" on this loop from the subscriber's dial to the *A* relay in the Director. This circuit is established after the line-finder, having found the calling line, extends the line to the primary selector, and the director hunter associated with that selector has found an idle Director. Other equipment in the primary selector is released though it is maintained busy to traffic.

Register Path

Register switches *1* through *7* are used one at a time in sequence to register and store the digits dialed by the subscriber for use in the control and completion of the call. Relay *A*, which is in the in-pulse path, will pulse following dial impulses on each digit, and close ground impulses over the register path by way of the *B* level of the sequence rotary switch to the proper registers, one register at a time. Relay *CA* will operate for the duration of each digit in multiple with the register switch in use, and when operated, relay *CA* closes the circuit to the sequence switch motor magnet. When each digit is complete and relay *CA* restores, the sequence switch is released and its motor magnet restores, driving its wiper ahead one step. When the third digit is complete and the sequence switch advances to its fourth bank contact, the Director has enough information in the 3-digit office code to request a translation and commence sending the directive digits necessary to reach the called office. This function does not require the full seven digits to have been registered. The subscriber will proceed to dial the balance of the digits while at the same time the Director will call for a translation, receive it, and commence sending.

Translator Path

The Translator path is called into the circuit at the completion of the third dialed digit by way of the fourth bank contact of level *C* of the sequence switch. This closes the circuit to relay *S* and relay *S*, when operated, initiates the Translator assigner operation, including the functions of relays *HA*, *HC*, *SC*, and *H*, and when relay *HB* operates, the Translator path is closed by way of the *ASR* bank and the *E* level of register *1* to one of the eight wipers of the Director code switch. The first digit dialed by the subscriber positions registers *1* and this position of register *1* selects which of the eight code switch wipers will be used. The second and third digits of the called office code, besides being registered on register switches *2* and *3*, also cause the vertical and rotary magnets to position the code switch shaft up and in to a position corresponding to the decimal values in the second and third digits. The path thus is closed by one of the eight code switch wipers and one of 800 code leads through the code assignment jumper field to bar relay *CL*, this relay having already been operated by relay *C*. The circuit is complete through relay *CL* and the translator jumper field to that Translator peculiar to the 3-digit office code which was dialed by the subscriber. The Translator relay operates. Certain of the 30 leads connected to the Translator will be grounded when the *TR* relay operates depending upon the directive required to reach the called office and resultant ground strapping on the Translator relay.

Directive Storage

The Director has, as part of its equipment, a group of relays, the purpose of which is to receive and store information from the translator for use as required. Relays *W11*, *X11*, *Y11*, *Z11*, and so forth, as well as the class and rate storage group, make up this equipment. When relay *H* operated on the translator function relay *BR* was closed and it operated. The various grounds closed by the translator over the 30-lead common are extended through the closed contacts of the *BR* relay to the directive and class and rate storage relays. The storage relays connected to those of the 30 leads which are grounded operate and lock, thus their own make contacts to ground at the *BB* relay.

Release of Translator Path

Whenever a Director calls for translation of an office code it is obvious that at least

one directive digit will be necessary to route the call. There may, of course, be other information too, but there must be at least one, and this first digit will be registered and stored in code group 11. Any one of the four relays in code group 11 will close a circuit to relay *SB* in the Director and relay *SB*, when operated and locked, opens the circuit to relay *S* in the Translator path. Relay *S* restores, causing relays *H*, *HA*, *HB*, *HC*, *SC*, *CL*, *TR*, and *BR* to restore. This whole cycle of operation covered under the Translator path, the directive storage, and the release takes but a fraction of one second, and as soon as these various units have been released they are available to other Directors requiring translation and directive information.

Pulse Generation

The Director is equipped with a step-by-step pulse generator designated *PG* on Figure 4, which, by means of its associated *MS* (motor start) relay, is started by the operation of relay *S* when translation was called for. The pulse generator is started as soon as translation is required so that it is up to speed and maintaining a constant speed prior to the time that output impulses are required for sending.

Sender Path

Once the directive has been received by the Director from the Translator, sending of step-by-step impulses by the Director via the primary selector and subsequent switch train may proceed one digit at a time under the control of relays *PA*, *PB*, *PH*, *PC*, and *PR*. The rotary switch designated "Send" is the primary control of each digit transmitted. When relay *SB* operated to initiate the release of the Translator path, it closed a ground-connected circuit over the sender path to the battery connected winding of the *A* relay in the primary selector. The selector *A* relay operates with subsequent selector seizure. The rotary transmission switch, designated "Trans" on Figure 4, has the function of supplying in code to the *C* and *D* levels of the send switch sending control information for each digit to be transmitted. This transmission rotary switch obtains its information one digit at a time by way of its *A*, *B*, *C*, and *D* banks from the code storage group. Having all of its relays in an idle condition after translation has been received, this group will be automatically skipped by the Translator switch when it reaches the bank position peculiar to that idle code group. Thus, no attempt is made by the Director to transmit digits other than those digits which are actually available for transmission. The sending cycle for a digit is as follows: relay *PA* operates from the operation of relay *SB*, closes a direct ground to the sender path and closes a direct ground to the magnet of the transmission switch and closes a pulsing ground to the magnet of the send switch. The transmission switch-magnet is energized and remains so until relay *PB* operates. The send rotary switch commences stepping one step for each operation of the *PR* relay and, after it has taken two steps, the next operation of the *PR* relay, besides advancing the send switch, also opens an impulse out on the sender path to the selector *A* relay. Each succeeding operating cycle of the *PR* relay will step the send switch and pulse the sender path until the send switch encounters on both its *C* and *D* banks indication that the required digit is complete. Relay *PC* will operate on this indication and close *PB*. Relay *PC* also will immediately short those contacts on the *PR* relay which have been impulsing the sender path. Relay *PB* operates and locks to the bank of the send switch *E* level and *PB* remains so locked until the send switch returns to its home (or normal) position. *PB* removes the direct ground from the sender path, places a multiple short across the *PR* relay contact, and leaves the sender path connected to the coil of the *PH* relay and the series resistor to ground. The circuit to relay *PA* also is opened at relay *PB* and relay *PA* restores.

A further result of the operation of relay *PB* is that the transmission rotary switch motor magnet is opened and it is allowed to restore and advance its wipers to the position of the new digit to be transmitted, if any, or, if the digit just completed were the last to be transmitted the transmission switch, by way of its *E* level, would advance to the position which indicates to the Director that sending is complete and that the Director now should release from the connection.

The purpose of relay *PH* in the sending control circuit for the sender path is to make the Director wait for a "sender signal" when a call is extended to a crossbar exchange. As soon as the sender in the crossbar equipment is ready to receive digit information as regards the called office and terminal number, the potential on the sender path is altered in such a manner that the *PH* relay restores. The Director then commences to send the digits as required.

Out-Pulse Path

The first digit transmitted by way of the sender path from the Director is always registered on the primary selector and, when the digit is complete, the primary selector will cut in on the first available trunk to the next switch. The wipers of the selector then are switched through directly to the connection established with the succeeding switch. Impulses of decimal value indicative of called office and terminal number are pulsed over the "ring" side of the out-pulse path to the outgoing trunk repeater. However, when a call has been translated as a short-haul toll call, and the calling subscriber has been identified by the Detector, ticketing information collected up to this moment by the Director must be forwarded to the Ticketer prior to the time that the Director is released from the connection. This data includes the calling station office third-digit code and four-digit terminal number, the class of service of the calling station, the called station office code and terminal number, the rate applicable to that called area, and the identity number of the Director used. This information is pulsed over the "tip" side of the out-pulse path at high speed at the same time that the switch positioning is being extended over the ring side of the out-pulse path to establish the connection. Relay *CP* transmits these coded pulses, which are collected by its associated rotary switch from the various storage points in the Director, such as the called station number storage, calling station number storage relays, and so forth.

Release

As soon as all digits necessary have been transmitted by the Director its presence is no longer required in the connection. Relay *TS* is operated from the *E* level of the transmission switch when all necessary digits have been transmitted. When relay *TS* operates, it opens the circuit which is maintaining the *F* relay in the primary selector operated as well as the *H* relay in the Director. The operation of *TS* and the restoration of relay *H* and of relay *F* in the primary selector will allow the Director to release in its entirety and will replace the calling subscriber's line forward by way of the primary selector in the out-pulse path and succeeding equipment to the final connection at the office wherein is located the desired terminal number. The Director now is available for other subscriber traffic.

No Discussion

Microwave Applications to Bonneville Power Administration System

R. F. STEVENS
MEMBER AIEE

T. W. STRINGFIELD
MEMBER AIEE

THE development of microwave radio has presented the power industry with a tool that promises to be most valuable. For many applications, it possesses important advantages, both economic and technical, over communication means heretofore available. In particular, its development came at a most opportune time for the Bonneville Power Administration (BPA), since use of the power line carrier by BPA and ten major interconnected power utilities had brought the available carrier spectrum practically to the point of saturation.

It was natural then that microwave had a prominent place in the BPA studies undertaken immediately after the war to work out a long-range communication program. These studies, however, were comprehensive in their nature, and considered all available types of channels, including:

1. Toll and Exchange Service
2. Leased Circuits
3. Government-Owned Wire Lines
4. Medium-Frequency Radio
5. Very High Frequency Radio
6. Power Line Carrier
7. Microwave Radio

No single type of channel was found to be superior for all applications. Each type was found to have some job which it could do best in an integrated system.

Toll and Exchange Service

It was obvious from the start that a simple extension from the nearest telephone company exchange was the sole solution needed for many of the small unattended stations. Toll calls from such stations are so infrequent that costs would generally be less than the annual cost on the investment which would be required for facilities to connect to the government system. Reliability and speed of service will vary with location but will generally be adequate for a station of this type. Maintenance men visiting the station will generally have radio equipped cars.

Toll and exchange service also is desired at the larger stations, for communication to points not reached by the government system. It will not constitute the sole or primary communication to such stations for operating purposes, however. Otherwise toll charges to a busy station would be prohibitive and speed of completing calls might not be adequate in emergencies. The importance of most such stations demands at least two alternate methods of communication, at least one of which would not be so susceptible to storm damage as open-wire telephone lines.

Leased Wire Circuits

Leased wire has economic advantages when used over short distances, particularly in urban areas. It has been used in a number of cases for such uses as pilot wire relaying and telemetering. It also is used by some of the interconnected power utilities in the area in providing connections between their dispatcher and the Bonneville communication system.

In many cases the reliability has been disappointing. Open-wire phone lines, and even cables, are more susceptible to damage from storms, floods, and other disasters than the rugged transmission cables used with power line carrier. Trouble, when it occurs, may be at a spot difficult of access, which is seldom the case with carrier. Moreover, in times of disaster, the power utility has its own personnel available on the spot to restore communications and this work is not in competition with work on other customers' services, as is the case for leased wire services.

In spite of this, because of the economic factor, it is expected that the BPA will continue to use a considerable amount of leased wire services for transmission over relatively short distances and in urban areas. However, the development of very high frequency (VHF) equipment provides an alternate which cannot be overlooked, and each application must be studied on its merits, with consideration given to both cost and reliability.

Studies of the BPA, like those of other utilities, have indicated that leased circuits are not competitive in cost with power line carrier over long distances. The same has been found to be true as compared to microwave, when the latter is properly applied.

Government-Owned Wire Lines

Because of susceptibility to storm damage and high maintenance cost, no government-owned wire lines are presently planned. Short sections of underground communication cable will be used, however, between substations and nearby microwave stations for distances of the order of a quarter of a mile.

Medium-Frequency Radio

Medium frequency radio is used by the Administration for communication between fixed stations and mobile units such as line trucks, and has generally been satisfactory. However, because of skip distance effect, the coverage of the region is somewhat erratic and occasional cases of interference have occurred. Two frequencies, 2,222 and 4,880 kc are available one being used for daytime and the other for nighttime reception. This is essentially a 1-channel system and will not be adequate when activities become more extensive and several conversations must

Paper 50-170, recommended by the AIEE Carrier Current Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing May 8, 1950.

R. F. Stevens and T. W. Stringfield are both with the Bonneville Power Administration, Portland, Oreg.

Figure 1. Cost comparison, power line carrier versus microwave, for average conditions on BPA system

Figure 2. Communication facilities for Pacific Northwest Federal Power System, with proposed extensions through 1954

be carried on throughout the region between fixed and mobile units. It is believed that it will be impossible to get assignments of other channels in this band. The amplitude-modulated equipment is susceptible to power line noise and cannot be used in the immediate vicinity of an energized high-voltage line as can frequency-modulated VHF equipment. The medium-frequency equipment also is limited in point-to-point communication for emergency use only and cannot be used for the transaction of ordinary business.

Very High Frequency Radio

VHF, because of its short range and fewer license restrictions, will overcome these disadvantages and the Administration plans to use it in the future for fixed-to-mobile communication. VHF equipment is normally frequency modulated and can be used in the vicinity of transmission lines where reception with our existing medium-frequency equipment would be completely blanked out by noise. An adequate number of channels can be provided. The first cost of each installation is considerably less than for the medium-frequency equipment now in use.

Because of the line-of-sight characteristics of VHF, fixed stations will have to be spaced at closer intervals. Fixed VHF stations will be installed at selected microwave station sites, making use of the existing towers and power facilities. These VHF stations will be connected to channels in the microwave system, thus extending the range of the mobile units to all points of the communication system, including the load dispatcher and other headquarters offices.

VHF, because of its relatively low cost, is well adapted for branches from the multichannel microwave system to substations where only one, or a few channels, are needed.

Power Line Carrier

Power line carrier was formerly the standard means of long distance communication used by most utilities for operation of their systems. Its application must now be evaluated in competition with the new medium, microwave radio, and in some cases, with VHF radio. For this purpose, a cost com-

parison was made several years ago, and is summarized in Figure 1. This curve is based on estimates made for running any number of channels from 1 to 12, over a route from Snohomish to Vancouver, Wash., and thence to Spokane. Terminal facilities were included at the important intermediate powerhouses and substations. In Figure 1, the cost of a simple carrier channel is taken as reference. Subsequently, the curve was corrected to reflect recent price decreases in microwave equipment. These curves should, of course, be used with caution by others, as the average conditions of the BPA network may not be typical of other systems. Nevertheless they illustrate the fact that microwave, with its high first cost and low incremental cost per additional channel, is best adapted to applications where many channels follow the same geographic route. Carrier, on the other hand, with its lower fixed cost and high incremental cost per additional channel, is better adapted to routes or branches where only one or two channels are required.

Microwave

The economic advantages of microwave relative to power line carrier have already been covered.

Microwave has a number of other advantages, including:

Channel reliability.

Ability to provide many channels on one carrier channel.

Freedom from interference.

Ease of maintenance.

Superior performance from the standpoint of noise, distortion and attenuation.

Full duplex communication without crowding of spectrum.

Availability of wide spectrum.

Ability to combine relay station sites with VHF for use with fixed-to-mobile communication.

Ability to use during construction prior to completion of connecting transmission line.

The principal disadvantage is that use of multiplex channels puts "more eggs in one basket." This encourages use of duplicate equipment and other means of gaining reliability, which are reflected in the cost.[4,2]

The BPA Communication Program

The most important part of the BPA communication program is shown in the map, Figure 2. This reflects decisions on channel types based on the factors just given, and, in particular, on the carrier-microwave comparison of Figure 1. It will be seen that microwave is to assume the burden over the backbone routes where channels are many, and carrier over the branches where the channels are few. Figure 3 shows the microwave and other radio facilities in service or planned for the near future; Figure 4, the same data for carrier current voice channels.

It is the intent that the existing carrier over the backbone routes will be retained, at least temporarily. If any or all of this should be found unnecessary, after the microwave proves its reliability, it can be transferred to new branch routes, and the original investment need not be lost. In considering purchase of new carrier, even for branch extensions, however, it will be necessary to evaluate it in competition with VHF radio. Such equipment will be available which will provide from one to several channels at a much lower basic cost than the multichannel microwave. Decision in each case will have to be made on specific local conditions, including type of terrain. It also will be influenced by technical developments and cost trends on both carrier and VHF.

Further details of the BPA system can best be discussed in terms of the services provided.

Telephone

Foremost consideration is given to providing circuits for system dispatching. Where economically feasible, telephone circuits will be provided for other functions depending upon access to the microwave system and power line carrier and radio extensions. Circuits will be provided in general as follows:

Chief dispatcher to each major generating station . . . one exclusive channel
one party line

Figure 3. Microwave radio system of BPA including equipment being installed or on order

Figure 4. Power line carrier current communication system of BPA, including proposed extensions through fiscal year 1951

Chief dispatcher to small generating station.....two channels either or both of which may be party line

Chief dispatcher to dispatchers of interconnected utilities.....one exclusive channel

Chief dispatcher to each subdispatcher.....two exclusive channels one party line

Subdispatcher to attended stations in area.....one party line

Maintenance headquarters to district maintenance....one party line

Administrative offices to district offices and other points.....one party line

Each party line will be limited to six stations.

In order to provide the telephone service just outlined, about 60 telephone circuits terminating at the J. D. Ross Substation will be required by the close of the next 6-year construction period.

Telemetering-Power

Telemetering is of major importance in providing "eyes" and "ears" for the load dispatcher, particularly for a complex job such as operating the BPA network in parallel with ten interconnected major utilities. As a result, the scheme shown in Figure 5 and Figure 6 has been worked out.

The complexity of the job is becoming so great that at least three subdispatching points will be required within a few years, to be located probably at Snohomish, Wash., Pasco, Wash., and Eugene, Oreg. (Goshen Substation).

Telemetering equipment now being installed provides for bringing information to the load dispatcher on the generation of Grand Coulee and Bonneville, the net kilowatt system interchange between BPA and Portland General Electric Company. Equipment to be ordered in the spring of 1950 will provide for telemetering of interchange with seven of the nine other major utilities. With many of these utilities, Bonneville has several interconnections each. Kilowatt readings of the separate individual interconnections with each utility will be brought to the appropriate future subdispatching point, and there totalized to give the net system interchange, which will be retransmitted to the main dispatcher at Vancouver. In addition, an extra channel will be available in the case of each utility so that a reading from a particular single interconnection point, which may be especially significant at any time may be selected and transmitted separately to the main dispatcher. It is hoped that arrangements also can be made to pick up from the load dispatcher's offices of the various interconnected utilities, readings on total steam generation and total hydro generation to the extent that these are available. These would be transmitted to the main BPA dispatching office, at which point the total steam generation, the total hydro generation, and the grand total generation for the entire Northwest power pool would be indicated and recorded. Channels can be made available to transmit this information back to such interconnected utilities as may desire it. Where outputs from some of the smaller

Figure 5. Schematic telemetering program of BPA

Figure 6. Telemetering program of BPA

Generation and system kilowatt interchange, showing use of microwave, carrier, and leased wire channels

generating plants are not telemetered, the equivalent information on the loads at these plants will be obtained from time to time by telephone and will be simulated by the setting of a potentiometer whose output is fed to the totalizing meters in the same manner as the actual telemeter outputs. Since the plants without telemetering are usually small, the errors from this method will have a negligible effect on accuracy of the recorded totals.

Figure 6 shows how microwave, carrier, and leased wire have been combined to provide the most economical channels for kilowatt telemetering.

At the dispatcher's office, Figure 12, a total of 50 recorders will be required to record power, river flow, voltage, and frequency. The system diagram board has been split to allow these recorders the most prominent position in front of the dispatchers' desks. (The two halves of the diagram board are designed so that they can be further separated as space for more recorders is required.)

Telemetering—Stream Gauge Readings

In addition to kilowatt telemetering, it is planned to telemeter river flow at four and ultimately six important points on the Columbia River. This information will be telemetered to the dispatcher's office in the form of river elevations, and there it will be automatically translated into second-feet-stream flow, in accordance with the calibration curves of the stream beds at the various gauging stations. Stream flow from all six stations will be recorded on a single chart having a semilogarithmic scale, Figure 8. In this way, water released from storage can be conveniently tracked during its passage down the river.

In addition to the gauging stations, the Administration now is co-operating with several other government agencies in developing a program for gathering and transmitting stream gauge, precipitation, snow survey, and temperature data. Figure 7 shows existing and proposed observation stations in the Columbia River basin from which the stream gauge data will be taken and sent to the collecting centers shown. Data thus collected will be transmitted, probably by teletype to the offices of the interested agencies in Vancouver, Wash. and Portland, for use in connection with power pool operation, flood control, and irrigation. The precipitation, temperature, and snow survey data is particularly useful for both short and long time forecasting of the run-off, knowledge of which also is required in planning and controlling water storage.

It has not yet been determined the extent to which automatic stream gauge transmitters will be used to replace or supplement observers who would telephone information to the collecting centers. It is felt, however, that automatic devices will be necessary at many locations. Studies are being made to determine the relative advantages of toll service, leased wire, and VHF radio for bringing information from the automatic gauges to the collection centers. This program is just getting under way, and several years will probably be required to develop it to the point shown in Figure 7.

A comparison of Figure 2 and Figure 3 with Figure 7 will show that the BPA communication system is well adapted for bringing in information from the collection centers to Portland and Vancouver. Conditions on the BPA are particularly favorable to the use of supervisory control. As a wholesale agency, many of its stations are extremely simple with only one or two secondary circuit breakers. Because its stations are relatively simple, and widely dispersed geographically, and because there is no distribution system to maintain, its operating personnel is normally spread quite thin. Many stations have only one operator, who obviously cannot be at the station 24 hours a day, seven days a week. Operation in such cases could definitely be made more reliable by supervisory control.

Some stations now unattended offer chance of improved service at reasonable cost with supervisory control.

Comparatively few supervisory control installations have been made to date, due primarily to lack of suitable channels. With the development of the microwave communication system, this will be remedied to a large degree. Use of VHF also is being studied.

Plans now are under way to increase the number of supervisory control installations from three to five in the fiscal year 1950, with four more to be added in the fiscal year 1951, and 12 in the fiscal year 1952. It is likely that supervisory lamp indication will also be provided in the main dispatcher's office to show position of all line breakers on the main 230-kv grid.

Power Line Relaying

Microwave has a major fundamental advantage over power line carrier as a channel for relaying, namely, because it is not necessary to assume that the channel may be out of service when the power line is faulted.

This permits an approach to the relay problem heretofore impossible—an ap-

proach which promises to decrease appreciably the time required to clear certain lines at both ends, and to decrease even more the minimum possible reclosing time.

The problem is so complex that it is impossible to evaluate precisely the gain in stable power limits throughout the transmission system, and the resulting value in dollars. However, preliminary studies indicate that this may be as much as several million dollars.[3]

Teletype and Facsimile

Teletype on a toll basis has been used for many years for communication between the Portland main office, the various district offices, and the Interior Department in Washington. It is felt that considerable use may be made of commercial facsimile service between Portland and Washington, D. C., should it ever become available on a toll basis. Teletype also is under consideration for bringing in river gauge information from the collecting centers mentioned previously.

Availability of high quality channels makes the use of facsimile also seem attractive, as the work of BPA is expected to become more and more decentralized, and there may be considerable need for transmitting maps and sketches between the main office and the various regional and district offices. Furthermore, its ability to transmit large tables of figures without possibility of error is very important. Three facsimile transmitter-receivers were purchased in 1946 for experimental use over carrier channels. However, the frequency response of most of our long carrier channels was inadequate. Some difficulty also was encountered in maintaining synchronism. These will be installed this summer on the microwave circuits where channel characteristics are more favorable. Studies will be continued to evaluate the usefulness of this and other types of facsimile equipment in power system operation.

Load Control

Load control channels have not yet been required by the Federal power system. The Northwest Power Pool is commonly operated with Grand Coulee powerhouse controlling frequency and with connected utilities using their automatic tie-line load control equipment to regulate their take of power. With the addition of more Federal plants to the two now in service, it is possible that some system may eventually be required to provide automatically for the most desirable division of load between the government plants under various conditions.

Fault Location

One of the most interesting and certainly the most novel BPA microwave application is to power line fault location.

Means have long been available to

Figure 7. Telemetering program of BPA
River gauge reporting stations, Columbia River Basin

measure quickly, accurately, and conveniently most of the quantities which must be known for the proper operation of a power system. Voltage, current, power frequency, river elevation, and many other quantities can be measured instantly, with great accuracy, and recorded at the site, or telemetered hundreds of miles for the information of the dispatcher.

In contrast, past methods of locating line faults have been almost unique in their slowness, cumbersomeness, and lack of precision. Even today, the commonest way of locating a sustained fault on a long line is to open sectionalizing switches and test line sections in turn until the fault is determined to be in one section, and then patrol that section, which may itself be 50 miles or so in length.

Many investigators here and abroad have been working on this problem in recent years and much progress has been made.[4,5,6] Engineers of the Bonneville Power Administration have worked on three different systems which have been described in part in earlier papers.[7,8]

After May 1950, when equipment now being completed is installed in the dispatcher's office, it is felt that an important milestone will have been passed. After that date, a fault occurring anywhere on a 200-mile section of the BPA network will cause its location to be printed instantly, in typed figures, on a paper recorder chart in the load dispatcher's office. Together with the typed distance in miles will be the time in hours, minutes, and seconds.

This is accomplished by the use of the recorder shown in Figure 15, together with a video timing pulse sent over the microwave system. Operation of the system is basically quite simple and is described in a previous paper.[7]

The time required to make the measurement is small indeed, though ample for the electronic methods used. Since 95 per cent of all faults are of the transient type not re-established when the circuit breakers are reclosed, and since it is desired to locate such faults as well as permanent faults, a measurement must be taken before the arc is extinguished. Since relay time may be less than a cycle (of the 60-cycle wave) and the circuit breaker will operate in less than three cycles, the equipment should be capable of operating in three cycles, or 50,000 microseconds. Actually, the measurement of distance is set up on an electronic counter within a few thousand microseconds.

The setting of the type wheels to correspond to the counter reading, being a mechanical operation, takes about three seconds. But, should another fault occur while the type wheels are being set up and are printing, the counter will receive and "remember" the second reading until the first reading is printed, after which the type wheels will be set to the new value which will be printed in turn on the chart.

A third signal received during the 3-second period will be lost; however, the chanee of three faults (or lightning "near misses" which might trigger the equipment) is considered rather remote. At least for the present, the addition of more elaborate memory features is not considered justified.

Data on the location of the fault is thus available, at the dispatcher's office, within three seconds after it occurs. Moreover, it is available in a form immediately usable. It is not necessary to wait for an oscillograph film to be developed. It is not necessary to call in an engineer especially skilled in the interpretation of a complicated trace. Information is available to an accuracy that could be obtained only with great difficulty, if at all, in the reading of a photographic film.

The initial installation is intended primarily to monitor the lines between J. D. Ross and Snohomish Substations. However, the equipment also will be effective to some degree in locating faults on certain other parts of the high-voltage network, as explained in a previous paper.[7] Complete coverage of the transmission system, however, is not possible with one installation.

It is proposed to add other locators, as the microwave system is extended, as shown in Figure 9. This will not only provide for essentially complete monitoring of the existing 230-kv network, but also will provide for check readings from two or more recorders for a large percentage of transmission faults.

Technical Requirements for Each Type of Service

The wide variety of communication services must each be examined in order to specify the performance of the multichannel microwave system.

In the interest of uniformity, all of the basic channels are specified alike and so far as practical designed to utilize equipment and practices that have evolved in the development of the communications industry. In accordance with this, the basic channel used is what is commonly termed a voice channel with a bandwidth of 300 to 3,000 cycles per second. A voice channel may be employed as a whole, submultiplexed, or combined with additional voice channels to accommodate specific service requirements.

Power Line Relay Protection

The transmission lines to be protected may be as long as several hundred miles. The microwave channels must transmit electrical quantities for comparison or transfer tripping or a combination of both. In order to provide channels suitable for use in conjunction with power line relay protection, the circuit characteristics provided are as follows:

Figure 8. Water flow telemetering program of BPA

Figure 9. Fault locator chart recorder showing location of recorders and remote and units to cover entire transmission network. Recorder number 1 only installed in 1950; monitors lines between Snohomish and Ross Substations

1. Output level constant within plus or minus 1 decibel over a period of one month to provide a reasonable maintenance schedule.

2. Output level constant within plus or minus 1 decibel when the radio frequency signal varies from plus 6 decibels to minus 30 decibels from the normal.

3. Recover immediately after a momentary loss of signal or power failure.

4. Continuity preserved during primary power outage.

5. Amplitude response linear within 1 decibel over a dynamic range of 30 decibels to allow comparison of electrical quantities.

6. Transient response such that the delay of a suddenly applied tripping signal in rising to 95 per cent of full amplitude is less than one-tenth of a 60-cycle-per-second wave.

7. Frequency response within ±1 decibel over the frequency range of 50 to 3,000 cycles per second. This permits the transmission of a 60-cycle signal for comparison purposes. The channel will transmit signals of frequency below 50 cycles per second with reduced amplitude but does not extend to zero frequency. The channel may be subdivided to provide three high-speed transfer tripping channels.

8. The frequency of a transmitted signal will be preserved absolutely to allow the channel to be used for phase comparison purposes.

9. Each channel has an output level of at least 4 decibels above 1 milliwatt, over a range of inputs of 0 to −12 decibels below 1 milliwatt and is provided with power level adjustments at both input and output.

10. To preserve uniformity of channels the requirements for noise, harmonic distortion and intermodulation distortion are based on telephony requirements which are more severe.

Telephony for Power System Dispatching

The microwave system is designed to provide telephone service over a circuit employing at least 32 repeater stations and six terminal stations connected in tandem over a distance of approximately 1,000 miles, in order to insure good quality communication between points at opposite ends of the Columbia Basin region.

1. Frequency response is flat within ±1 decibel over the range of 300 to 3,000 cycles per second.

2. The total rms harmonic distortion in each channel for one hop consisting of two terminal stations is limited to 3.5 per cent with full channel modulation. Practically all of this distortion is produced in the modulating and demodulating equipment at the terminal stations and practically none in the repeater stations. It is expected that at least six terminal stations may be connected in tandem. With linear addition of the distortion products, the over-all distortion would be 21 per cent; with rms addition it would be 8.6 per cent. It is expected that the distortion will be between these two figures. If the distortion produced in each terminal equipment is similar (same order harmonic), as may be caused by limiters, tests have shown that the distortion may be minimized by polarizing the patch cords to buck out the harmonic when connecting stations in tandem.

3. The weighted signal-to-noise ratio in each channel for the link is limited to 50 decibels. As the number of repeater stations and terminal stations connected in tandem increases, the channel signal-to-noise ratio will decrease depending upon the relative amount of noise contributed by the radio equipment and multiplexing equipment. The conditions of fading in the various links may be the determining factor. Under normal conditions the channel signal-to-noise ratio will be determined by the multiplexing equipment and for six in tandem will be approximately 43 decibels. It is expected that there will be some deterioration with time depending on maintenance.

4. The signal-to-cross talk ratio in each channel will be at least 56 decibels which minimizes the effect of intelligible cross-talk. Since the signal-to-cross-talk ratio is at least 56 decibels, the specified 50-decibel signal-to-noise ratio is protected against unintelligible cross-talk.

Fault Locating on Transmission Lines

The video channel employed for the purpose of fault location on the power transmission system will transmit, when demanded, a single randomly occurring video pulse of approximately two microseconds' duration and with rise and decay times of approximately one microsecond. This channel employs the entire microwave bandwidth momentarily at the time of transmission of the pulse, without causing a noticeable interruption to the other services.

Other Services

All of the basic channels provided by the microwave system will have essentially the characteristics as set forth for power line relaying and telephony. This provides high quality channels for other services such as telemetering, supervisory control, and teletypewriter for which the requirements are not as severe. One or more of the standard channels may be submultiplexed to provide these additional services, the number per standard channel depending upon the transmission

Figure 10. Snohomish microwave station—a typical BPA microwave station using equipment in the 1,700–1,850 megacycle band

speed required. Facsimile would normally employ one channel; but if a higher transmission speed were required, two or more standard channels may be combined.

The versatility and economy of a microwave radio system in meeting diversified communication requirements make the application of microwave to the BPA power system an important contribution to its reliability and efficiency of operation.

Transmission Paths and Profiles

The propagation of radio waves at microwave frequencies through the atmosphere is being studied by many investigators.[9–16] While much is still to be learned about the causes of propagation

Figure 11. Typical pulse train for 8-channel system using pulse time modulation, as installed on Ross-Snohomish link. Shows double synchronizing pulse, single narrow channel pulses, and wide fault locator pulse. Can be expanded to provide 23 channels

anomalies, sufficient data of an empirical nature have been gathered to give reasonable assurance that a high degree of reliability may be attained on overland paths. A study of the data and discussions presented by the foregoing investigations yields information which is useful and may be used as a guide in locating transmission paths and specifying equipment. These are briefly tabulated as follows:

1. Vegetation causes severe attenuation.
2. Normal atmospheric refraction cannot be depended upon.
3. Reverse beam bending is quite common during the night hours in the summertime.
4. Severe fading may result from interference between the direct and ground-reflected wave caused by tropospheric effects and depending upon the smoothness of the intervening terrain.
5. Severe fading may result from multipaths caused by atmospheric refraction.
6. Frequencies of approximately 7,000 or eight thousand megacycles appear to be the upper limit for protection against excessive attenuation caused by rainfall and employing reasonable radio-frequency.
7. The longer the path, the more severe is the fading caused by atmospheric anomalies.
8. There is a tendency for the fading to be more severe as the wavelength is shortened.
9. During rainy or stormy weather tropospheric conditions are not conducive to fading.
10. Fading occurs more frequently during the summer months particularly during conditions of high humidity and relatively quiet atmosphere.

In consideration of the foregoing, the BPA system was laid out observing the following conditions:

1. All transmission path profiles are based on true earth's radius, rather than 4/3 earth radius.
2. Beam clearance is based on tree-top level.
3. Minimum beam clearance of 100 feet is maintained in the midpoint region of the path with greater clearance provided, when practicable, on the longer paths.
4. Vertical space diversity reception is employed on all paths longer than 30 miles.
5. Equipment is designed to accommodate a 30-decibel fade or a 6-decibel rise from normal free space transmission level over a transmission path 60 miles in length.

As a result, it is believed that the circuit operation will be reliable to a degree necessary for its use in connection with the operation of the power system and that circuit outage due to propagation anomalies will be less than 0.01 per cent of total operating time.

In laying out the transmission paths between points of communication, cost of access roads and site preparation severely limited the choice of sites. Sites therefore were always chosen near existing roads and fortunately, it has been found so far that in such cases commercial power is generally available nearby.

Preliminary selection of sites and transmission paths was made by use of United States Coast and Geodetic Survey maps in conjunction with aerial photographs. Over unsurveyed regions, preliminary

Figure 12. BPA load dispatcher's board showing central location of telemeter recorders. Fault locator to be mounted at right end of dispatcher's desk

Figure 13. Microwave transmission path profile, South McNary Dam to Kennewick, Wash.

profiles were made by photogrammetric means using aerial photographs and a stereoscopic plotter. All critical points where the amount of clearance was in doubt were then checked in the field. It was found that in general, optical line of sight cannot readily be established or checked by visual observation because of haze or nearby intervening objects which would normally be cleared by the tower. It was found to be most practical to check critical points by accurate instrument survey. Actual propagation tests were not employed, first, because of the expense, and second, to be of value the test should be run for a period of at least one year, since reception of a signal does not necessarily indicate attainment of optical line of site, and certainly would not prove that the desired clearance had been obtained.

Towers

Towers used for all links are the self-supporting steel type. Those in the Vancouver-Snohomish link are of standard Forest Service type with stairways to the top as shown in Figure 10, a design originally selected with the thought the radio-frequency equipment might be mounted at the top of the towers at some stations. When equipment for the other links was placed on order, it was found that the use of fewer and smaller antennas decreased wind loading to the point where smaller towers were practical. At the same time, it was decided to eliminate stairways in favor of ladders with protective guards. The over-all result was a reduction in weight of nearly 50 per cent. Standard policy is to mount all equipment except antennas, on the ground, even though this results in considerable additional cost, in some cases, for coaxial cable or wave guide. It is felt that the saving in extra convenience offsets this added cost.

Buildings

Prefabricated buildings made from aluminum panels are used for the smaller radio station houses. Larger buildings are of concrete block construction.

Radio-Frequency and Multiplexing Equipment

The portion of the system now under construction or on order includes three main links; the Ross-Snohomish link, 200 miles in length, connects the Portland-Vancouver, Wash., headquarters with BPA substations and dispatchers of interconnected systems in the Puget Sound area, also with the BPA Seattle District Office. The Ross-Spokane link connects the Portland-Vancouver area with Spokane by way of the Columbia River federal power plants (Bonneville, McNary, Chief Joseph, and Grand Coulee), other utility dispatchers, and important intermediate substations. The Snohomish-Columbia link connects the north end of the Ross-Snohomish link with an intermediate point on the Ross-Spokane link. This provides a direct routing for protective relay channels for the transmission lines which cross the northern Cascade Mountains. It also completes a loop which makes possible alternate routing of traffic to a large number of the stations on the system, in the event of propagation or equipment failure at any point on the loop.

Equipment for the Ross-Snohomish link was purchased from the Federal Telecommunication Laboratories and will be in operation in June 1950. The equipment for the rest of the system was recently purchased from the Philco Corporation and should be in operation in the fall of 1951. Both companies are supplying pulse modulation systems, that of Federal Telecommunication Laboratories being pulse-time modulated, and that of Philco being pulse-amplitude modulated. The Federal equipment operates in the government band between 1,700 and 1,850 megacycles, and the Philco equipment in the 7,125- to 8,500-megacycle government band. The principal characteristics of the two systems are tabulated in Table I. Figures 10 and 12 show views of a typical station on the Ross-Snohomish link.

Stand-by radio-frequency equipment with automatic change-over in case of failure is provided throughout the system. On the longer paths, the stand-by radio-frequency receiver is connected for vertical space diversity reception.

To facilitate maintenance, a service

Table I

	Ross-Snohomish Link	Ross-Spokane and Snohomish-Columbia Links
Manufacturer	Federal Telecommunication Laboratories, Inc.	Philco Corporation
Frequency band, megacycles	1,700–1,850	7,125–7,425
Oscillator	Lighthouse triode	Klystron
Frequency stability, per cent	±0.05	±0.05
Transmitter output, watts	10	1.0
Receiver bandwidth, megacycles	8	8
Receiver noise factor, decibels	14	14
Polarization	Horizontal	Horizontal and vertical
Large antenna		
Diameter, feet	10	6
Beam width, degrees	3.5	2.2
Gain, decibels	33	40
Small antenna		
Diameter, feet	6	4
Beam width, degrees	5.5	3.5
Gain, decibels	29	36.5
Type of modulation	Pulse time	Pulse amplitude
Pulse repetition frequencies, cps (sampling rate)	8,000	8,000
Ultimate channel capacity per radio frequency carrier	23	32
Channel bandwidth, cycles	300–3,400	300–3,300
Frequency response of each channel	+1 to −2 decibels	+1 decibel to −1 decibel

channel will provide automatic transmission of failure alarms to the terminal stations to indicate on lamp alarm panels loss of transmission and primary power failure at any repeater station with station identification. The service channel also serves as a party line telephone circuit throughout the system. As a supplement to the automatic alarm, it may be used to localize faults to the particular station involved by means of the selective dial system.

Power Supply

Each microwave station will be supplied with primary power either from a commercial source if it is a remote repeater station or from the station service bus of the nearby BPA substation to which it is providing terminal facilities. Because of the likelihood of prolonged power outage at the remote locations during storms, a gasoline engine driven generator set is provided at each repeater station.

The starting time of the gasoline engines ranges from one half to several minutes.

The microwave system will provide channels for power line relay protection of the power transmission lines, and it is therefore essential that it keep operating continuously during the time of system faults.

Since a fault on the BPA power transmission system may affect the station service supply and also the commercial power supply at the repeater stations through interconnection, a means for providing uninterrupted power at the time of system faults must be provided at each microwave station.

The size of the load varies from approximately 2 to 15 kw depending upon the type and size of station, the lowest demand being taken by a simple repeater station and the highest value for a repeater station with several radio branch circuits. Terminal stations and repeater stations with terminal facilities have a power demand between these extremes depending upon the extensiveness of the terminal facilities. Approximately half of this load consists of plate supply and the remaining half of tube heaters. The d-c plate supply voltages range from 200 to over 1,000 volts. The heater load because of thermal storage can withstand switching from one power source to another, but in general, the plate load has insufficient electrical storage to allow a switchover which may be of the order of 0.1 second.

A continuous source of power will be provided by means of a storage battery and a continuously rotating machine consisting of an induction motor, d-c machine and synchronous generator at all stations. At the larger stations, in order to reduce the size of the induction motor, only the d-c plate load is fed from the motor-generator set and the tube heater load is normally fed from the primary station supply. The battery floats on the d-c machine which furnishes a trickle charge. Upon failure of the primary supply, the rotational inertia of the set is sufficient to maintain service until the d-c machine motors. The heater load is automatically transferred to the synchronous generator. At repeater stations the microwave load is automatically transferred from the synchronous generator to the gasoline driven generator after a predetermined time of perhaps 10 minutes. The momentary interruption of approximately 0.1 second during this switching transfer is of no consequence since the power line relaying function should have been accomplished by that time.

Microwave Systems for 960 and 2,000 Megacycles

R. V. RECTOR
MEMBER AIEE

W. E. SUTTER
NONMEMBER AIEE

OUR modern civilization has grown extremely dependent upon reliable continuous communications. The vast communication networks of our public utilities will verify this statement. Some have expanded their present communication systems of phone lines, power-line carrier, and mobile radio to a point where additional expansion is extremely difficult. They are turning, therefore, to a fourth system that will help fulfill their expanded requirements. This new system is microwave radio and is the subject of this paper.

Many articles have been written of late on the subject of microwave communications. The words microwave and relaying, multiplexing and pulse modulation have been introduced into our daily conversation and appear in all our current technical literature. Wartime developments in tubes (such as Klystrons, lighthouse tubes, magnetrons, crystal mixers) and in high-frequency circuit design have enabled the communication field to expand into this new frequency spectrum.

The Federal Communications Commission has recognized that microwaves offer a solution to these congested fields. The bands available for point-to-point use by power companies and industrial services are in the 900-, 2,000-, and 6,000-megacycle regions. Present indications tend to make the 952–960 megacycle and the 2,000-megacycle bands the most advantageous. Each band has its own independent applications.

Where a very large number of voice channels are required, it is economical to use the 2,000-megacycle band or higher. The equipment necessarily requires the wide transmission bandwidth available in this region. It seems that for economical reasons, the 2,000-megacycle band is more desirable than the 6,000-megacycle band.

For a number of reasons, the most promising place and the recommended portion of the spectrum for a low cost radio link with a small number of channels and a few relay points appears to be in the 952–960 megacycle region. The equipment has the advantage that it is similar and more closely related to techniques employed in equipment of the low frequencies. It is relatively high frequency, yet standard tubes may still be used. Portions of the 920–960 band are presently assigned for frequency modulation broadcast studio transmitter links. Economical multiplexing of up to seven channels may be obtained on this equipment.

Propagation of microwaves follow very different laws than the waves of the low-frequency bands. They, in general, do not bend nor follow the curvature of the earth. They tend to travel in straight lines similar to beams of light and therefore reliable communications require a line-of-sight path clearing the surface of the earth by some reasonable distance. In actual application, advantage should be taken of hills and tall buildings, see Figure 1.

Because of the short wave lengths, relatively simple antennas can be used to transmit the energy in a beam. Six-foot metallic parabolic reflectors produce beams as narrow as 6 degrees in width at 2,000 megacycles. With this concentration of energy, low power transmitters may be used. Transmitters of 5 to 20 watts are employed enabling simplicity in design and longer trouble free operation. Figures 7 and 8 show a typical transmitter and receiver. Their simplicity will be apparent.

Let us now investigate a typical 2,000-megacycle relay system, such as presented in Figure 2. The major components are:

1. Transmitter Terminal
2. Microwave Transmitter
3. Transmitting Antenna
4. Receiving Antenna
5. Microwave Receiver
6. Receiver Terminal

For simplicity the system shown provides communication in only one direction. A similar system working in the opposite direction would give us 2-way communication. Where greater than line-of-sight distances are to be covered, a relay point or points consisting of a receiver feeding directly into a transmitter may be employed.

When more than one signal is to be transmitted over this system, the signals are said to be multiplexed. This is the function of the terminals. Two systems are available today to accomplish this multiplexing: time division multiplexing; and frequency division multiplexing.

For systems of a small number of channels, frequency division is conventional. For larger systems, time division is used. Here the signals of the various input channels are sampled individually several thousand times a second. The voltage sample at the moment determines some characteristic of the pulse.

Systems using pulse position, pulse amplitude, and pulse length are a few now commercially used. In actual practice, the number of necessary samples can be greatly reduced by passing the demodulated audio voltage through a low-pass filter to attenuate harmonics and thus reduce the distortion at the highest modulation frequencies. Obviously, if the samples are taken at a constant rate, the lower audio frequencies will be sampled

Paper 50-171, recommended by the AIEE Carrier Current Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing May 10, 1950.

Figure 1. Beam transmission path

Figure 2. Typical 2,000-megacycle relay system

many more times, in proportion, and thus will inherently have lower distortion. Laboratory measurements have shown that a low-distortion system can be obtained with as few as three samples of the highest modulation frequency. In a practical application for telephone communications, the highest audio frequency is about 3,500 cycles per second, and thus the sampling rate should be about 10,000 times per second.

It is the function of the transmitter terminal to produce all these modulated pulses at the correct time, and feed them to the microwave transmitter, and it is the function of the receiver terminal to take the output of the microwave receiver and route the pulses to the correct output channels.

Let us now take a look at two examples of commercial microwave equipment. First a 2,000-megacycle link. In Figure 3, we see a block diagram of the transmitter terminal. Briefly, the transmitter waveform generator produces waveforms that basically time the over-all system. The timing circuits are all based on a 300-kc crystal controlled oscillator. It then governs the production of the timing pips, sawtooth, and a synchronizing pulse.

The output of the 300-kc oscillator is coupled to a pip generator to produce sharp spikes of voltage. In one branch they are amplified, while in the other they are used to trigger a frequency-divider multivibrator. The frequency divider, triggered at a 300-kc rate, has a 10,000-cycle output and is used to key the synchronizing generator. The synchronizing pulse thus produced is used to trigger the sawtooth generator. The first two waveforms, namely the sawtooth and timing pips, are fed to the respective modulator chassis to be used in the channel selector circuits, along with a variable positive voltage, obtained from a voltage divider.

Each of the channel selectors is arranged to select one particular reference pip. The particular reference pip for each channel triggers the multivibrator to generate a pulse, which is length modulated. Therefore, each channel produces a pulse after each synchronizing pulse in a fixed sequence. The audio signals are fed through an amplifier and limiter stage and coupled to the pulse modulator circuit. The action of this modulating circuit on the pulse generator produces an output that varies in width in accordance with the samples taken of the input signal.

The pulses are mixed in the amplifier shown in the upper right of Figure 3, along with the synchronizing pulse, and are then fed to the transmitter and

Figure 7. Microwave transmitter mounted in temperature-controlled cabinet

Figure 8. Microwave receiver mounted in temperature-controlled cabinet

beamed to the distant receiver. This signal is then fed to the receiver terminal equipment, Figure 4. Specifically, it is fed to the receiver waveform generator where it is utilized to form timing pips and sawtooth synchronized with the pips and sawtooth at the transmitting terminal.

The sawtooth and timing pips are used, together with a variable bias, to produce a predetermined delay in firing of the gate generator. This gate is fed to the screen, and allows only one of the pulses from the train to appear on the plate, and there be demodulated.

The length modulated pulses are first converted to the equivalent amplitude-modulated pulses and then combined by a peak detector to reproduce the original audio voltage. Audio is then fed through a low-pass filter and coupled through an amplifier to the output lines.

That basically is the multiplexing system. Of course, certain refinements are added, and in Figure 5, the complete terminal is shown. The left cabinet is the transmitter terminal, and the right cabinet is the receiver terminal. The center cabinet contains the basic control chassis along with all the power supplies.

The similar units appearing here in the transmitter and receiver cabinets are the modulating and demodulating units respectively, 12 of each consisting of two channels per chassis. It is rather easy to add channels and expand the system after initial installation. The larger panels in the two outside cabinets provide constant monitoring of input and output channels. In Figure 6, a view of the rear of the three cabinets will show the construction and the availability of parts and ease of maintenance.

In Figure 7 is shown the microwave transmitter. The 2,000 megacycle radio-frequency output is obtained from a type *SRL-7C* Klystron power oscillator. Rated at 10 watts, it is operated in this application from 2 to 5 watts for longer life and greater reliability. Because of the cavity construction, excellent frequency stability is obtained by accurate voltage and temperature control. Frequency sta-

Figure 9. 960-megacycle transmitter

bility of 0.05 per cent is obtained. The Klystron radio-frequency output is matched to the transmitting antenna by a double slug dielectric matcher, and thus no moving finger or contacts are used in the entire radio-frequency system.

Carrier shift modulation (frequency modulation with pulse modulation) is accomplished by modulating the Klystron reflector voltage by the pulses generated in the terminal and amplified by the video modulator. The remainder of the panel is power supplies.

The entire transmitter is housed in an insulated, weather-resistant cabinet equipped with blowers and a thermostatically-controlled damper to automatically maintain the cabinet temperature. The microwave receiver, Figure 8, is a self-contained single-conversion superheterodyne carrier shift modulation receiver.

The *SRL-7C* Klystron is used as the local oscillator. Conversion is accomplished by a silicon crystal located in a specially-designed mixer. The mixer is matched to the antenna with a dielectric matcher.

Figure 11. 960-megacycle transmitter, front view

The intermediate frequency amplifier (bandwidth of 8- and 60-megacycle center frequency) provides six stages of intermediate-frequency amplification and two limiter stages. Double fixed tuned circuits are used throughout to provide excellent adjacent channel selectivity. Sensitivity of 95 decibels below 1 watt is obtained.

The receiver is housed in a cabinet of a type similar to that used for the transmitter.

Neglecting the antennas, that covers the basic equipment for a 2,000-megacycle microwave relay system. A system of this nature is capable of transmitting 24 channels of audio (200–3,000 cycles) with less than 3 per cent distortion, and having noise and cross-talk ratios of better than 50 decibels.

Let us briefly compare a typical 960-megacycle relay. In Figure 9, the basic circuits are shown in the block diagram of the transmitter. Basically, it is a typical frequency-modulated transmitter consisting of a reactance tube modulator which frequency modulates an oscillator operating at a center frequency of 5.4 megacycles. This is mixed with a signal derived from a quartz crystal controlled oscillator in two consecutive stages and then fed through three doubler stages. This multiplication gives us a signal of approximately 960 megacycles with a frequency swing of ±75 kc for 100 per cent modulation and output power of 10 watts.

In Figure 10, we have the block diagram of the receiver. The first converter is used to convert the signal power from the carrier to the frequency of the first intermediate frequency, 112 megacycles. This local oscillator is a crystal oscillator with tripler, and doubler stages follow-

Figure 10 (left). 960-megacycle receiver

Figure 12 (below). 960-megacycle receiver mounted in cabinet with other audio facilities

Figure 13 (above). Microwave channel equipment

Figure 14 (below). Microwave multiplexing equipment

ing. The second converter gives us a second intermediate-frequency of 10.7 megacycles and feeds two limiter stages followed by a discriminator and final audio stages.

The performance of this equipment fully meets all the requirements of the Federal Communications Commission for program relaying, and, therefore, lends itself very aptly to multiplex transmission because of high stability, low noise, and a flat frequency response for a large audio band with extremely low distortion. In Figures 11 and 12, we see the manufactured product.

Microwave radio systems have already

Figure 15. Microwave multiplexing equipment

proved their reliability, especially during storms when wire communications were disrupted. This reliability, plus the low cost per channel, will make microwave relaying the answer to many present communication problems.

Multiplexing Methods

The microwave channel provided by either of the two previously described equipments can be employed to provide multiple simultaneous subchannels. This division of the main channel into a number of subchannels is commonly called multiplexing. As you will have noted, multiplexing equipment is available for the 2,000-megacycle equipment to provide a time-division method of multiplexing. However, frequency-division multiplexing apparatus also may be employed with this 2,000-megacycle equipment. The 960-megacycle equipment described provides multiplexing by means of frequency-division apparatus only.

By means of multiplexing apparatus all of the services normally associated with the operation of a power system may be obtained. That is, subchannels can be provided for the simultaneous transmission and reception of communication, directional-comparison relaying, phase-comparison relaying, automatic supervisory, telemetering, and load-control signals.

The 960-megacycle microwave channel has modulation capabilities up to 30 kc. Within this 30-kc band, we can fit multiplexing apparatus to perform the previously listed services. Figure 13 illustrates a basic 2-way 960-megacycle channel to which has been added relatively simple and inexpensive multiplexing gear. The figure illustrates one unusual feature in that the outlying stations B and C lie within the 20 degree beam width of the signal from the control station A thereby permitting one transmitter and antenna at A to communicate with and control both stations B and C. The multiplexing apparatus in this figure consists of a direct voice channel and four channels of supervisory control and telemetering which are obtained by audio tone units. The voice channel uses frequencies below 3,000 cycles, the control and telemetering functions use frequencies above 3,000 cycles. High-pass and low-pass filters, as indicated, serve to separate the frequencies above and below 3,000 cycles and thereby prevent mutual interference between the communication and control functions. Additional filtering in each control channel provides selectivity between the four control functions. The 4-wire audio input-output circuits of the communication channels are combined in a hybrid balancing circuit of the multiplexing equipment to provide a 2-wire telephone circuit which may be connected to existing *PBX* facilities. The resulting services obtained consist of communication between stations A, B, and C (between B and C through *PBX* facilities at A), supervisory control between A-B and A-C, and telemetering of one quantity each from B to A and C to A.

A more elaborate and complex use of

Figure 16. Transmission and reception of power line carrier-current channels

multiplexing apparatus on 960-megacycle equipment is illustrated in Figure 14. This illustrates a frequency division of the 30-kc modulation capability into seven subchannels, one consisting of direct voice modulation and six derived from telephone-type carrier apparatus employing carrier frequencies of 8, 12, 16, 20, 24, and 28 kc. Each of the seven subchannels will provide a 2-way voice circuit having a frequency range of 300 to 2,500 cycles, or each channel may be used to provide 18 2-way control channels. Each of these 18 control channels may be used for the transmission or reception of intelligence requiring frequencies no higher than 30 cycles. This narrow bandwidth is adequate for conveying the intelligence required by all types of telemetering, load control, supervisory control, and directional-comparison pilot relaying. Phase-comparison relaying intelligence would require a bandwidth of ±60 cycles which would occupy the space of two of the narrow (30-cycle) control channels. An examination of Figure 14 illustrates that a very great number of multiplexed services may be simultaneously transmitted over a 960-megacycle microwave channel.

The same type of frequency-division multiplexing may be employed with 2,000-megacycle equipment, however, its greater modulation capability of up to 4 megacycles makes it more economical to obtain even a larger number of multiplexed services by means of a time-division system of multiplexing. As described previously, time-division multiplexing gear is available for use with the 2,000-megacycle equipment which will provide 24 2-way voice channels, each capable of a 200-to-3,500-cycle frequency range. Likewise, each of these 24 channels may be used to provide a maximum of 18 2-way control channels, each of which may be used for the transmission or reception of frequencies up to 30 cycles such as required by telemetering, load control, supervisory control, and directional-comparison pilot relaying. Figure 15 illustrates multiplexing of this type. As mentioned in connection with the 960-megacycle equipment, the transmission and reception of phase-comparison relay intelligence would require a bandwidth of ±60 cycles corresponding to the space requirements of two of the 30-cycle control channels.

Another use of the 2,000-megacycle microwave equipment consists of utilizing its 4-megacycle modulation capabilities for the transmission of power-line carrier-frequency channels in the range of 30 to 200 kc. Such an application would be involved in transferring intelligence received on a power line carrier channel from a terminating substation to an uptown office. An illustration of this application is shown in Figure 16 in which the power-line carrier apparatus, usually located at the transmission line termination, would be installed at an office location within a city. Operation of this channel from the power line to the

substation to office would be as follows:

The carrier frequencies (30-200 kc) conveying three communication channels and three telemeter readings would be taken from the power line through the usual coupling capacitors and applied through radio frequency amplifiers to the microwave channel for sending to the office location. At the office location, the customary demodulation of the 2,000-megacycle signal would again produce the original 30-200 kc carrier frequencies which would be demodulated in the carrier-current equipment to reproduce the required intelligence. Operation of the channel from office to substation to power line would be similar. The voice and telemeter intelligence would be applied as modulation of the 30-200 kc carrier-current frequencies. The carrier-current frequencies in turn would be used to modulate the 2,000-megacycle channel equipment. At the substation demodulation of the 2,000-megacycle frequency would reproduce the modulated 30-200 kc carrier-current frequencies which would be amplified and applied to the power line through coupling capacitors.

By use of this method, it is evident that all of the carrier-current frequencies which would normally be expected to terminate at a power station location may readily be extended to terminate in an office location remote from the power line termination.

Consideration of the foregoing multiplexing possibilities indicates that the use of microwave equipment can provide many reliable and useful channels for the transfer of all types of intelligence associated with the operation of a power system.

Discussion

R. H. Miller (Pacific Gas and Electric Company, San Francisco, Calif.): This paper gives a very good exposition of the relative advantages and limitations of 960-megacycle and 2,000-megacycle microwave systems as well as describing typical commercial versions of presently available equipment for each of these bands.

In the discussion of time-division multiplexing methods a comparison of pulse length, pulse position, and pulse amplitude systems might have been of general interest. It was noted also that no reference was made to pulse code modulation, and this method of muliplexing might have been covered briefly. In the selection of a modulation system for the time-division multiplexing equipment described in the paper, the reasons for the selection of pulse length modulation was not discussed. There must have been certain salient features of this system that led to its selection and an outline of these reasons would have been helpful to the reader.

In discussing the frequency stability of the Klystron oscillator the figure given for stability is 0.05 per cent. This figure seems rather low as compared to lower frequency equipment and the question is raised as to whether or not the figure given is correct or perhaps a typographical error.

In comparing frequency-division and time-division multiplexing methods it should be pointed out that one of the reasons that a favorable signal-to-noise ratio is available from a time-division multiplex system is that all of the energy of the radio signal is available in the channel being sampled while in a frequency-division system the radio-frequency energy is divided among the various channels. This factor itself, as well as bandwidth limitations, on 960 megacycles, limits the number of channels practically usable on a frequency-division multiplexing system.

The authors of this paper have done a particular service in suggesting various applications of microwave equipment in the power industry. By combining voice communications, relaying, telemetering, and so forth in one microwave system, considerable economy can be effected. The only undesirable feature that might be suggested to such a system is the fact that failure of the microwave equipment might prove very serious if many such important functions are carried on one microwave system.

W. H. Blankmeyer (Montana Power Company, Butte, Mont.): To one who is more directly interested in microwave application than in the actual technical research phase of this equipment, the general program of microwave development is very interesting. This paper, in listing relative characteristics of 960- and 2,000-megacycle equipment, shows that these two systems contain, in general, all the requirements of any microwave system while achieving them economically. At the present state of the art, the lower frequency techniques are attractive and have the advantage in that respect where fewer channels are acceptable. The idea of deliberately making use of the normally wide beam of 960-megacycle equipment for multiple receiving locations seems useful for some power system applications. However, as the authors mention, the choice of 960- versus 2,000-megacycle equipment depends entirely on requirements of a specific application with respect to number of channels, both present and future, as well as to the other factors mentioned.

Microwave development in general is meeting intense interest from power utilities because conventional facilities are saturated and yet we are faced with a steadily rising demand for multiple channels offering the utmost in reliability.

The trend toward centralized control of power stations makes us aware of shortcomings in some types of channels now being used. It appears that we have in microwave communication a means of establishing new standards and approaches to our remote control problems.

At least, microwave equipment requires maintenance at definite locations as compared to physical lines, and it provides plenty of interference-free channels of all types.

Most power system communication engineers agree that microwaves will serve as a main stem of a composite system made up of all other facilities now being used. In other words, microwaves probably will not create obsolescence so much as promote much needed expansion and modernization up to the required level of present operating problems.

A microwave feature especially useful in power systems is the idea of piping conventional carrier current frequencies by microwave beam along with other channels. This compares somewhat with the successful practice of transferring carrier current signals directly from power lines to telephone lines or vice versa, to permit strategic placement of carrier current terminal equipment.

Although relative cost analysis of various communication methods is difficult to make by hypothesis, surveys indicate that multichannel microwave installations can provide service at an annual cost per channel mile much below that of private wire, carrier current, or leased circuit. This analysis takes into account first costs, interest, amortization, return on investment, taxes, and maintenance probability.

The annual cost per channel mile of microwave decreases as the number of channels or length of microwave terminal separation increases up to the point of repeating for any reason. Consequently, at some length of microwave hop-length the down-sloping cost curve of microwaves will cross through the essentially flat cost rate of private wire or leased circuit. For this reason channel mile costs of a well-engineered multiple channel microwave system can decrease to a fraction of telephone wire communication costs. While carrier current has some advantage over straight wire costs, it also fails to meet the challenge of microwaves where a high number of channels is involved.

R. V. Rector and **W. E. Sutter:** In reply to R. H. Miller's inquiry concerning the reasons for the selection of pulse-length modulation, it may be well to point out some of the advantages obtained from this system. In any time-division multiplexing system, one of the most difficult problems is that of obtaining circuits that will remain stable over a long period of time and be almost completely independent of tube and temperature variations. The pulse-length system described in this paper provides synchronization from the front edge of each pulse and thus the tolerances or drift of the pulse positions do not alter the adjustments of the channel selector circuits. This advantage is not available in a pulse-position system in which synchronization is obtained only on the single synchronization pulse at the beginning of each pulse chain. In addition a pulse-length modulation system does not require linear amplifiers and does provide good noise elimination characteristics as a result of the pulse-clipper circuits. These advantages are, of course, not available in a pulse-amplitude system.

Mr. Miller also questioned the 0.05 per cent frequency stability figure of the 2,000-megacycle equipment as being rather low.

This figure is correct and in general is considered satisfactory. The wide bandwidth of this type of equipment makes the stability characteristic less important than is the case in systems which have less bandwidth available.

Oral discussion following the presentation of this paper indicated considerable interest in this type of equipment to perform the services required in the operation of utility system. In view of this interest, it is probably advisable to mention some additional features and some of the improvements which have been incorporated in the 2,000-megacycle per second equipment since the original writing of this paper.

Because of numerous inquiries concerning the possibility of transmitting the complete functions of a telephone system, it will probably be of interest to note that the equipment does contain circuits for the transmission of the d-c functions required by automatic telephone exchanges (PAX) and the ringing functions of trunk line telephone circuits and does therefore lend itself readily to this type of application.

This equipment now has been redesigned to provide a more economical arrangement for a small number of channels, such as 2 to 12. The 24-channel equipment described in the paper did not economically lend itself to applications requiring less than 12 channels.

The employment of the Klystron tubes has recently been eliminated in favor of crystal-controlled equipment using less expensive triode tubes. This elimination of the Klystrons permits the use of a less expensive transmitter and receiver housing and permits the equipment to be located at a much greater distance from the antennas. A distance of as much as 350 feet may now be used between the transmitter-receiver and the antennas. In many cases this distance may be increased if necessary.

Ignitron Converters for High Energy Particle Accelerators

J. L. BOYER
ASSOCIATE AIEE

C. R. MARCUM
ASSOCIATE AIEE

THE need for larger magnet power supplies for high energy particle accelerators has resulted in a new application for power conversion equipment. It uses rectifier equipment which can either supply power or return power to a flywheel a-c motor-generator set. The equipment is unusual in that the current flows in one direction, but the polarity of the output voltage is reversed to change the direction of power flow.

The magnet used on a large proton-synchrotron requires the current to build up rather slowly to a maximum value. To save the energy stored in the magnetic field and restart the cycle in a short time, the current in the magnet must be forced to zero by a counter voltage. The acceleration of particles is accomplished in the current build-up period, and this is the most critical portion of the load cycle. In the two units to be described, the current build-up in the magnet is roughly linear with time and the current decay has about the same characteristics.

A rectifier and a-c motor-generator set for a large magnet has been manufactured for the Brookhaven National Laboratory. This equipment has a peak kilowatt rating of about 30,000 kw with a pulse rate of 12 per minute. The second installation is at the University of California Radiation Laboratory in Berkeley, and this unit is rated 100,000 kw peak with a pulse rate of about ten per minute. The rectifier equipments for both of these installations are described in this paper. Since the two installations are so similar, only the data on the University of California equipment will be given.

Paper 50-174, recommended by the AIEE Electronic Power Converters Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 16, 1950; made available for printing April 25, 1950.

J. L. Boyer and C. R. Marcum are both with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Requirements of Magnet Power Supply

The magnet load on the power supply appears as a tremendous inductance in which the time constant is about 15 seconds at small currents. When a direct voltage is applied, the current starts to build up at a constant rate. The build-up time on the University of California unit is approximately 1.9 seconds. After the peak current is reached, it is desirable to bring the current to zero in a minimum time to reduce the losses.

It is necessary to have very accurate control of the direct voltage at the start of the pulse since the injection of the protons occurs at a low magnet current, and the problem of holding the particles is most difficult at this time. The ripple in applied voltage must be low. It was decided that a 12-phase rectifier voltage ripple is satisfactory, but no ignition control can be used because of the increase in harmonics in the d-c output voltage.

Special consideration was required on the problem of never attempting to open the magnet circuit when any current was flowing. The inductance is so high that if any of the equipment would attempt to suddenly change the current, a very high voltage would be produced, and the magnet and other equipment might be damaged.

The load variation taken from the power source had to be kept to a minimum so that the disturbance on the power system would be within the required limits. It was, therefore, necessary to have some energy storage equipment such as flywheels on the motor-generator sets.

Advantages of Rectifiers over D-C Machines

In the original investigation of the best type of power supply for these large magnets, d-c motor-generator sets and rectifiers with a-c motor-generator sets were compared. It was found that the time required to suddenly reverse the polarity of a large d-c machine was so great that a considerable extra loss would result while the magnet current was near the peak value. With rectifiers, the time required to change from rectification to inversion can be as short as 1/2 cycle, and even on the more complicated circuits which correct many mechanical problems, it is only a few cycles.

The problem of completely reversing the field current of a d-c machine twice each pulse and accurately controlling the voltage at the start of each pulse appeared to be extremely difficult if not impossible. With rectifiers, a minimum of field control is used on the a-c generator to make it possible to control the rectified voltage with extreme accuracy at the start of each pulse.

Rectifiers with an a-c motor-generator set proved to be more economical than a d-c motor generator. The higher voltage rating of rectifier tubes make it easier to obtain the high voltages desired for the magnet coils. The type of rectifier which is used on these applications is shown in Figure 1.

Rectifier and Inverter Circuit Operation

Since it was necessary to obtain a rather high direct voltage, four rectifier units are operated in series. Figure 2 shows the complete power circuit for the University of California installation. Two identical units are operated in parallel to give the desired rating.

Each generator Y supplies six ignitron tubes which operate with balance coils to form a 3-phase rectifier. Figure 3 shows

Figure 1 (left). High - voltage ignitron rectifier assembly. Eight such assemblies have peak power output of 100,000 kw

Figure 3 (right). Wave shape of 3-phase ignitron converter direct voltage during changeover from rectifier to inverter operation

the operation of one 3-phase rectifier in the period at the peak current, when the operation is changed from rectifier to inverter. On the left side of this figure, the tubes are operating with zero degrees delay. This current commutates from one tube to the next with a rather long angle because of the relatively high reactance of the generator windings.

The change from rectifier to inverter operation occurs when the ignition point is suddenly delayed approximately 100 degrees. This causes the tube which was conducting the current at that instant to continue for an extra long angle, and the other tubes start to conduct the current mostly on the negative half of their alternating voltage wave.

In the inverter portion of the pulse as indicated on the right of Figure 3, the tubes are fired considerably in advance of the negative crossing point of the alternating voltage waves. This is to allow for a rather long commutation angle and to give the tubes some margin angle so that they will gain control before the anode goes positive. Some extra angle is allowed so that there can be a considerable unbalance in load current between the two units.

Tube Development

The selection of the type of rectifier was based on the requirements for high voltage and heavy direct currents with

Figure 2 (left). Power circuit of magnet power supply for University of California bevatron

Figure 4 (below). High-voltage pumped-type ignitron

Figure 5. High-voltage excitation cubicle which operates at cathode potential of the ignitron rectifier assembly

Figure 6. Low-voltage excitation cubicle which operates at ground potential

both rectification and inversion duty. Pumped ignitrons were used rather than sealed ignitrons because pumped tubes have a higher ratio of peak current to average current, will withstand rougher treatment, and have a much longer life. The basic ignitron design is based on a tube which was developed for 3,000-volt railway substation applications.[1]

With the circuit shown in Figure 2, the duty on each ignitron is such that it is required to carry an average current of 261 amperes and a peak current of 2,083. At the start of the rectification period, the crest inverse voltage is 9,430 volts, and at the peak load it is 7,920 volts. During the inverter portion of the pulse, the crest forward voltage on each ignitron is 7,350 volts at the peak load and 9,430 volts at no load.

A tube similar in design to one which had proved successful for rectifier operation in commercial 3,000-volt railroad service was chosen for this application. Since the duty on the ignitron involved inverter operation and unusual loading conditions, laboratory tests for approximately 20 weeks were made to assure the best internal design for this application.

Figure 4 shows the cross-section of the double grid ignitron which was developed for this application. The tube has two ignitors and a voltage is applied to both at the same time to keep the number of ignitor misses to an absolute minimum. All paths between the cathode and anode are made as open as possible to allow the tube to conduct extremely heavy current with a relatively low arc drop with little probability of arc surges. The main anode bushing uses a glass-Kovar seal to hold vacuum and a heavy porcelain bushing to provide mechanical strength.

A glass-Kovar seal is used on the connectors to the two grids. For the high inverter currents used in this application, the outer grid is used as an excitation and shield grid, and the inner one is used as a control grid. By having both ignitor and grid control, heavy current can be controlled.

Excitation Circuits and Control

Those control circuits for the rectifiers which do not require a definite phase relation with respect to the generator voltages are supplied from a station 460-volt auxiliary bus. The power for the excitation circuits must have a definite phase relationship with the generator voltage. They obtain voltage through a step-down transformer with its primary connected to the generator terminals. A station battery is used for the essential control.

As much of the excitation circuit as possible is operated near to ground potential. Certain parts of the circuits must necessarily be operated at the rectifier cathode potential. A high voltage excitation cubicle is associated with each rectifier assembly and is electrically connected to the cathode of that assembly. This cubicle, shown in Figure 5, houses the ignitron grid circuits, insulating transformers, and vacuum control circuits. The ground potential part of the excitation circuits for two series rectifier assemblies is housed in a low-voltage excitation cubicle, shown in Figure 6.

The excitation circuits for one ignitron is shown in Figure 7. The ignitron firing circuit obtains power from a charging transformer which charges the firing capacitor through a thyratron. The charge on the capacitor is held until the grid releases the firing thyratron and then discharges through the primary of the ignitor coupling transformer to fire the ignitor. A short circuiting metallic rectifier on the secondary prevents saturation of the ignitor coupling transformer.

The instant of firing of the ignitor is determined by the control of the grid of the firing thyratron. This circuit consists of two peaker windings in series with a constant negative bias and a positive control bias. The peaking transformer pulse phased at the desired rectifier firing angle has a low-peak voltage, and the peaking transformer pulse phased at the desired

inverter firing angle has a high-peak voltage. With no positive control bias impressed, the negative bias bucks out the low-peak voltage but permits the high-peak voltage to release the tube at an inverter firing angle. When the positive control bias is impressed in series with the negative bias, the resulting bias is reduced so that the low-peak voltage releases the tube at a rectifier firing angle. The phase positions of the peaking transformers are determined by the power connections to the primaries and by a direct current in their phase shift windings.

In order for the ignitron to conduct when the ignitor is fired and its anode voltage is positive, its grids must be released. The outer grid is excited from two windings of the grid insulating transformer which are 90 degrees out of phase and connected through metallic rectifiers. This circuit makes the outer grid positive when the ignitor is fired at either the rectifier or the inverter angle. The inner grid is negatively biased until the outer grid current starts to increase and causes it to be released by a positive voltage on the grid coupling transformer between the outer and inner grid circuits. A misfire light is connected across the inner grid resistor and when lighted indicates that current is flowing to the inner grid. This further indicates that the outer grid has picked up and that the ignitor has fired.

The control and protection of the vacuum and cooling systems and the method of degassing these rectifier assemblies is much the same as for any standard rectifier application and will not be discussed in this paper.[2]

The rapidly increasing current in the magnet during the rectifying period is limited by the length of time that the positive control bias is applied to the excitation circuits. In order to limit the peak current in the magnet, a timing relay with a drop-out time of approximately 110 per cent of the desired rectifying period is de-energized as the positive control bias is applied. If the positive control bias has not been removed within the dropout time of the relay, contacts on the relay will automatically remove it. Further overload protection is obtained from inverse time over-current relays which are connected to the secondary of current transformers on the generator leads.

The generator and the ignitrons must be protected from occasional faults of the ignitrons. In case of an arc-back, there is a local short circuit involving the generator and the rectifier that arced-back caused by some ignitron conducting current in the reverse direction. An instantaneous overcurrent relay connected to the secondary of the generator lead current transformer energizes a relay which short circuits the output of the ignitor excitation circuit and thereby suppresses the arc in the forward-conducting ignitrons which are feeding the short circuit. It is then expected that the inductance of the magnet will force the reverse current in the faulty tube to zero. If the short-circuit current is reduced to a reasonable value, the short-circuiting relay on the excitation circuit will open and allow the ignitrons to operate again. If the short-circuit current is not limited by arc suppression within a few cycles, an inverse time overcurrent relay will energize a switch short circuits the magnet and will trip a high-speed circuit breaker in the field of the generator to remove the voltage from the ignitrons and thereby clear the fault.

If, during the inverter operation, an ignitron should have an arc-through, the current that can flow in the tube is limited to the magnet current. The tube with the arc-through will have a current twice its normal value since the current in the parallel circuit will transfer. Even with twice normal current in the tube, it has a good chance of regaining control the first few cycles after the arc-through occurs, so no instantaneous protection is applied. If the tube should not regain control within a few cycles, a relay, connected through a circuit sensitive to 60 cycles across the d-c terminals of each rectifier assembly, trips the magnet short-circuiting switch and opens the field circuit breaker of the generator.

Arc-back indicators are provided so

Figure 7 (left). Schematic of excitation circuit for one ignitron tube

Figure 8 (below). Typical load cycle for the University of California magnet power supply

that the number of arcbacks occurring on each ignitron may be recorded. For each ignitron there is a small thyratron with a d-c plate supply and with its grid connected to an impulse coil on the anode lead of the ignitron. Reverse current on the ignitron will release the thyratron and thus record the arcback.

Load Cycle

A typical load cycle for the magnet power supply is shown in Figure 8. The particle acceleration takes place during the rectifier operation which is the first 1.9 seconds of this cycle. This part of the cycle is most critical and must be repeated as closely as possible from cycle to cycle.

Interphase transformers are provided between parallel units so that synchronous operation of the two generators will not affect the output voltage. The interphase transformers are designed with very low exciting currents so that by the time the magnet current reaches a value at which the particles are injected, the interphase transformers are fully excited. An electronic regulator working on an electronic exciter assures that the generator voltage is the same at the start of each cycle.

A master control device applies the positive control bias to start rectifier operation. As the magnet current reaches a predetermined small value, the particles are injected into the vacuum chamber at a speed corresponding to the field strength of the magnet. As the magnet current increases, the master control device causes the particle to accelerate at a rate matching the rate of increase of the magnetic field strength. After the particle has reached the desired speed, it is deflected from the vacuum chamber, and the master control device removes the positive control bias. This allows half of the series units to change to inverter operation. An internal positive bias in the excitation cubicle keeps the other half of the units operating as rectifiers for approximately one-half cycle of the generator shaft resonant frequency. At this time the remainder of the units change to inverter operation. This small time delay accomplished by using a timing commutator on the end of the generator shaft tends to cancel the stresses in the generator shaft that would be obtained with an instantaneous full power reversal. In approximately 2.1 seconds of inverter operation, the magnet current has been brought to zero. With high magnet currents, the inverters must be fired with considerable angle of advance in order to have sufficient deionization time for the tubes. This angle of firing must be delayed as the current approaches zero so that the output voltage of power supply is zero when the current reaches zero. This is accomplished by means of phase shifting windings on the inverter peaking transformers which are controlled by the load current. After the current reaches zero, there is a short off-time and the cycle is repeated.

Conclusions

Although these magnet power supplies are the first of this type and quite large, even larger units can be built without serious complications. Experience obtained with these two installations should give valuable engineering information on the performance of high-voltage pumped-type ignitrons when operating as the total load on an a-c generator.

Multistation Supervisory Control, Telemetering and Communication on Single-Frequency Carrier Channel

W. A. DERR
MEMBER AIEE

T. C. WREN
NONMEMBER AIEE

J. V. KRESSER
MEMBER AIEE

POWER-LINE carrier and associated equipment was recently placed in service by the Sierra Pacific Power Company for the centralized control of part of the system. In planning this centralized control system, consideration was given to the use of telephone line wires, power-line carrier, and microwave radio to provide the necessary interconnecting channels. Economic considerations led to the selection of power-line carrier.

This first use of power-line carrier equipment on the Sierra Pacific Power Company system exemplifies the efficient use of carrier equipment by combining multistation supervisory control, selective telemetering, and communication on a single-frequency channel. A multistation supervisory control system is one in which more than one station is operated from a common set of equipment at the controlling station. The system to be described requires no audio tone modulating equipment since only a single signal receiving relay is required at the controlling location and at each controlled location.

Power System

Figure 1 is a partial single-line diagram of the Sierra Pacific Power Company system, showing the stations involved in this centralized control installation. The approximate direct line and transmission line distances between the stations also are shown in Figure 1.

Equipment now is in service which provides for the remote operation of the Farad Hydro Station, the Verdi Hydro Station, and the Virginia City Substation. The equipment recently installed provides for the control of these three stations from the Washoe Hydro Station. All system dispatching is done from the Washoe Hydro Station. This remote control system will be extended to include another station in the near future.

The Farad Hydro Station has two 1,750-kva generators providing a normal output of 2,900 kw and 2,100 kilovars. The power house at Farad is shown in Figure 2. The Verdi Hydro Station has one 3,000-kva generator providing a normal output of 2,300 kw and 1,200 kilovars. The output of the Farad Plant is determined by the forebay level at Farad. The output of the Verdi Plant is determined by the river level. Both plants carry base load which must be adjusted periodically to conform to the water level. The water level at both stations is determined by the flow of water in the Truckee River. The kilovar output of the plants is determined from the system voltage conditions.

In Figure 3, the carrier, supervisory control, telemetering, and communication components which have been applied at the Washoe, Farad, and Verdi Hydro Stations and the Virginia City Substation are shown in block diagram form.

Power-Line Carrier Equipment

Exact duplicate standard carrier assemblies are installed at each of the four locations shown in Figure 3. These standard assemblies are exactly the same as those which are applied for carrier relaying of the distance measuring type.[1,2] The assemblies also are duplicate of those used for phase comparison relaying except for the omission of a control unit which is required for phase comparison relaying.[2] All of the carrier equipment is operated from 125-volt station batteries.

The carrier equipment at each location is mounted on a standard relay rack in an indoor-type cabinet. The assembly consists of individual transmitter, receiver, and modulator panels and a test meter unit. Figure 4 shows the carrier cabinet located in the Washoe Hydro Station. The equipment rack shown can be swung open to provide access to the rear of the units.

The transmitter panel consists of a Colpitts oscillator (one tube) and a 6-tube push-pull amplifier. The amplified carrier frequency output is fed into an iron-cored radio-frequency transformer whose secondary couples the carrier to the line through the line tuning unit and coupling capacitor. The transmitter has a frequency range of 50 to 150 kc and a frequency stability of 0.5 per cent. The transmitter has a nominal power output of 10 watts.

The receiver panel consists of a narrow-band saturated receiver and a broad-band receiver. The narrow-band receiver is used for all unmodulated carrier signals such as supervisory control and telemetering impulses. The broad-band receiver is suitable for the high quality reception of speech. The frequency range of both receivers is 50 to 150 kc. On this installation both receivers are tuned to the same frequency. The narrow-band receiver will operate through an attenuation of 30 decibels when used with a 10-watt transmitter. The broad-band receiver will operate through an attenuation of 50 decibels when used with a 10-watt transmitter.

Paper 50-175, recommended by the AIEE Carrier Current and Substations Committees and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing April 25, 1950.

RENO JUNCTION AND GEIGER GRADE	9.5 MILES	10.0 MILES
GEIGER GRADE AND VIRGINIA CITY	5.5 MILES	6.5 MILES

Figure 1. Partial single line showing part of system involved in carrier installation

The modulator panel has relays, voltage dropping resistors, and a telephone handset jack mounted on it. It is designed for use with a push-to-talk telephone handset. The voltage dropping resistors furnish proper microphone current and operating voltages for the relays. The various relays and contacts are wired so that the carrier transmitter can be keyed when the telephone push-to-talk key is operated.

The test meter unit is a portable assembly of instruments for routine circuit testing. It can be mounted in the carrier cabinet. The test meter unit is shown near the top of the carrier cabinet in Figure 4. All of the carrier panels have test jacks in the main circuits to provide for the measurement of currents and voltages with the test meter unit.

The power-line carrier equipment operates from phase-to-ground. As shown in Figure 3(A), the carrier transmitter and receiver at Washoe are coupled to the 60-kv lines to Farad as well as to the two 60-kv lines to Virginia City. Single-frequency carrier line traps are installed in each of these lines so that an essentially fixed impedance is presented to all carrier signals regardless of switching operations at Washoe. This is the only location at which carrier line traps are used. The carrier equipment is coupled to both 60-kv lines between Washoe and Virginia City to obtain additional reliability.

Since no attenuation data was available and since there is no other carrier on the system, it was arbitrarily decided to try operation at a frequency of 100 kc. A satisfactory signal was obtained at all locations and the system is still operating at this frequency.

There was no problem involved in tuning the parallel circuits at Washoe. The 4-line tuners are each connected to the carrier equipment by a separate coaxial cable. Each of the lines was tuned independently of the others and it was found that the division of the radio-frequency current was fairly even. No difficulty is anticipated when another line out of Washoe is added to this carrier system for the control of a fourth station.

A satisfactory signal is obtained at Virginia City with either of the two 60-kv lines out of service.

Supervisory Control Equipment

The supervisory control equipment applied is of the direct selection all-relay coded impulse type.[4] This type of system employs a series of impulses transmitted at the rate of approximately 15 per second for all selection and control codes. Check or verification codes are used to insure proper selections. This type of system requires only a single signal receiving element at each station. Only such a single-signal system can be used for the control of several stations on a single-frequency carrier channel.

The supervisory escutcheons are arranged in a mimic bus arrangement at the Washoe Hydro Station to depict the essentials of the power system. An individual escutcheon is provided for the control and supervision of each circuit breaker, for each selective telemetered indication, and so forth. An individual escutcheon for the control of a circuit breaker is shown in Figure 5. The selection pushbutton is located at the bottom of this escutcheon. The selection lamp is above the selection pushbutton and the two upper lamps indicate the circuit breaker position. The position indicating lamps are omitted on the escutcheons for selective telemetering.

Figure 6 shows the supervisory control panels in the Washoe Hydro Station.

Figure 7 shows the supervisory control installation in the Verdi Hydro Station. Part of the power-line carrier cabinet can be seen at the right of this figure.

The supervisory control provides for the control and supervision of the circuit breakers at Virginia City Substation and for all of the essential functions at the Farad and Verdi Hydro Stations. The supervisory control also provides a selective telephone ringing function to each of the controlled stations.

Functions at Verdi Hydro Station

Following is a complete list of the functions provided at the Verdi Hydro Station. Each such complete function is usually referred to as a point of the supervisory control.

1. Start-stop control of generator with supervision of master relay.
2. Control of generator field rheostat with telemetering of kilovar output.
3. Control of generator governor synchronizing motor with telemetering of generator kilowatt output.
4. Control and supervision of 60-kv circuit breaker.
5. Control and supervision of generator circuit breaker.
6. Telemetering of forebay water level.
7. Supervision of alarms for which generator shuts down.
8. Supervision of alarms which do not shut down generator.
9. Telephone ringing.

Telemetering Equipment

Impulse-type telemetering equipment is used for the selective telemetered indications listed previously.[5,6] Rate of impulse telemetering equipment is used for the indications of kilowatts and kilovars.

The rate of impulsing is between 80 and 220 per minute. The left-hand reading on the receiver is obtained with a rate of 80 impulses per minute and the right-hand or full-scale reading is obtained with a rate of 220 impulses per minute.

Since the readings are selective, a single transmitter is used at the Farad and Verdi Hydro Stations for telemetering kilowatts and kilovars. The supervisory control equipment connects the transmitter to the proper potential and current transformer circuits. A reactive component compensator is automatically connected in the potential circuits to the transmitter by the supervisory control equipment for telemetering kilovars.

At the Washoe Hydro Station, a single receiver is provided for all kilowatt indications and a single receiver is provided for kilovar indications.

Duration of impulse-type telemetering equipment is used for the selective indications of water level. The transmitters are of the pressure-bulb type. With this system, the reading obtained is based on the length of impulse transmitted during each 5-second cycle.

Figure 2. Powerhouse at Farad Hydro Station

Automatic Switching Equipment

In providing for the remote operation of the Farad and Verdi Hydro Stations it was necessary to add certain automatic switching and protective equipment at each of these stations.[7] The method of operation provided for the two stations is somewhat different.

At the Farad Hydro Station, an automatic electronic synchronizer, a speed matcher, and a voltage-balance relay are provided. Upon receipt of a starting signal from the supervisory control equipment, all of these devices are automatically connected to the generator to be started. Thus the speed and voltage of the generator are automatically made to match the system frequency and voltage. The automatic synchronizer causes the generator circuit breaker to close when the instantaneous frequency difference and the phase-angle difference are satisfactory for proper synchronizing.

The control of the Verdi Hydro Station is based on all synchronizing being done on the circuit breaker at the Washoe end of the line. Therefore, no automatic synchronizing or speed matching equipment is used at the Verdi Hydro Station. The operator at the Washoe Hydro Station is able to start the generator at the Verdi Hydro Station and to individually control the generator and line circuit breaker. The operator also can control the speed and voltage of the generator at the Verdi Hydro Station to be able to effect manual synchronizing of the circuit breaker at the Washoe Hydro Station.

After the generators at the Farad and

Figure 3. Block diagram showing carrier, supervisory control, telemetering, and communication components at (A) Washoe, (B) Farad and Verdi, and (C) Virginia City

Figure 4. Power-line carrier cabinet in the Washoe Hydro Station

Verdi Hydro Stations are connected to the system, the operator at Washoe can control the kilowatt and kilovar output of the machines.

Operation of Remote Control System

The supervisory control system applied in this centralized control installation can provide for an ultimate of 100 functions or points. Two series of impulses, both of which are automatically checked, are required for the selection of each individual point. The first series of impulses selects a group of ten points and the second series of impulses selects the individual point in the group of ten points. The necessary number of groups to provide for the desired number of functions are assigned to a particular station.

The two series of impulses required for the selection of an individual point are designated as group and point selection codes. The corresponding check or verification codes are designated as group and point check codes. In this installation, the minimum number of impulses for any group selection code is seven. This eliminates the possibility of any actual group selection resulting from random interference which could operate a carrier receiver relay. The corresponding group check codes are in all cases six impulses less than the group selection codes. The point selection and point check codes are the same and may have from one to ten impulses. Since the impulses are transmitted at the rate of approximately 15 per second, the longest selection time for any point of the ultimate system is less than four seconds.

The group selection codes now in use are as follows:

Verdi—7 and 8 impulses.

Farad—9 and 10 impulses.

Virginia City—11 and 12 impulses.

If a selection key is operated at Washoe, the group and point selection codes originate at Washoe and the group and point check codes originate at the station selected. In the case of an automatic operation reporting from one of the remotely controlled stations, the group and point selection codes originate at the remote station and the group and point check codes originate at Washoe.

For control functions and for the supervision of devices, similar series of impulses are used. The number of such impulses is the same for all points since only one point can be selected at a time.

Figure 6. Supervisory control panels in the Washoe Hydro Station

Since the carrier transmitters and receivers are tuned to the same frequency at all locations, keying a transmitter at one or more locations results in operation of the single-carrier receiver relay at every station. This party-line arrangement makes it possible for the supervisory control to select a particular station and to simultaneously lock out all other stations. The group selection code is recognized as a lockout code by all stations except the one being selected. These stations remain locked out until a reset impulse is transmitted from Washoe at the end of a complete function. The re-

System Restored to Normal At-Rest Condition			

set impulse is approximately a quarter of a second long. Receipt of a carrier impulse of this length or longer at any station releases a point which may have been selected at that station or unlocks that station if it had been locked out by selection at another station. A reset impulse restores the entire supervisory control system to its normal at-rest condition so that it is ready for selection of another station.

Table I(A) indicates the impulsing which results if the circuit breaker at Virginia City Substation which is assigned a group selection code of 11 impulses and a point selection code of three impulses is selected and closed. Table I(B) indicates the impulsing for the automatic tripping of a circuit breaker at Farad Hydro Station which is assigned a group selection code of nine impulses and a point selection code of one impulse.

As indicated in block diagram form in Figure 3, the supervisory control relays at each station are interposed between the carrier equipment and all of the services provided. This makes it possible to give preference to the important supervisory control functions rather than to the telemetering or communication services.

Selective Telemetering

Operation of a point selection key for any of the selective telemetered indications, results in the automatic transmission of group selection, group check, point selection, and point check codes of impulses as described for the selection of a circuit breaker control point. However, at the conclusion of the point check code, the proper telemetering transmitter has its keying contact connected to the carrier transmitter and the proper telemetering receiver is connected to receive the carrier impulses. Thus, an indication is obtained immediately after the point is selected.

The circuits are arranged so that the telemetering impulses, which are long with respect to the length of the supervisory control impulses, do not cause the point to be released either at the Washoe controlling station or at the controlled station selected. However, the telemetering impulses do reset the other controlled stations which were locked out when the group selection code was transmitted.

The telemetered indication may be maintained as long as desired. Operation of the reset key results in the supervisory control reset impulse being transmitted at the termination of a telemetering impulse which may have been in progress at the time. Operation of the carrier receiver relay at the station selected without the telemetering transmitter contact being closed results in the selected point being released and the entire system restored to normal.

In the case of points in which a control function is combined with the selective telemetering, the control impulses from the Washoe Hydro Station are transmitted during the off period of the telemetering impulses. The control is of the increment type with the control circuits at the controlled station being energized for a definite period of time for each operation of a control key at the Washoe Hydro Station. An arrangement is provided so that the control increment for each of the devices controlled is individually variable. It is possible for the operator at the Washoe Hydro Station to accurately obtain the desired kilowatt and kilovar output of the generators since a telemetered indication is obtained while the controlling is being done.

Since the continuous transmission of carrier from any station with such a single frequency carrier system would make the entire system inoperative, a timing circuit is provided to automatically disconnect a telemetering transmitter which keys the carrier transmitter continuously due to a failure in the telemetering transmitter or loss of alternating power on the transmitter.

Communication

The supervisory control provides for selective ringing from the Washoe Hydro Station to any of the three stations controlled. It also provides for any of the controlled stations calling the operator at

the Washoe Hydro Station. The telephone ringing is accomplished by points of the supervisory control.

A telephone deskset and a telephone call and answer box is located in the Washoe Hydro Station. The call and answer box has a telephone key and lamp for each of the controlled stations. To initiate a telephone call from Washoe, it is only necessary to operate the telephone call key for the desired station, and to lift the telephone handset from the cradle. This results in the automatic transmission of the proper group and point selection codes from Washoe and the corresponding check codes from the station being called. When the point check code is received at Washoe, a control code is automatically transmitted to ring the telephone bell at the station being called. When the call is answered by the removal of the telephone handset from the cradle at the called station, a supervision code is transmitted which is followed by a reset impulse from Washoe to restore the entire supervisory control system to the normal at-rest condition. When the supervisory control equipment resets, circuits are completed from the telephone to the carrier equipment at Washoe as well as at the station called. This establishes communication of the push-to-talk type between Washoe and the station called. Operating the push-to-talk key on either telephone handset keys the carrier transmitter at that location and the telephone transmitter can then modulate the carrier. This is the same type of communication which is provided on the usual single-frequency carrier protective relaying installation.

Calling the operator at Washoe from one of the controlled stations is accomplished in a similar manner. It is only necessary to remove the telephone handset from the cradle at the controlled station to initiate a call to Washoe. The telephone at the controlled stations is mounted on a supervisory control panel as shown in Figure 7. When the supervision code is received at Washoe, the telephone bell is sounded and the call lamp indicating which station is calling is lighted. To answer the call, the operator removes the telephone handset from the cradle and operates the telephone call key for the station making the call. The supervisory control system than resets automatically and conversation can start.

With this communication system it is possible for the operator at Washoe to perform the necessary ringing functions to establish communication between two or more of the remotely controlled stations.

After communication is established, the supervisory control system is locked out while a telephone push-to-talk key is operated at any of the stations. However, the supervisory takes control at the first instant that no telephone push-to-talk key is operated. Thus, if a circuit breaker is tripped by a protective relay operation at any station, it will report its new position to Washoe in the usual manner at the first pause in the conversation. The first supervisory control impulse disconnects the telephone from the carrier equipment at each station and prevents the starting of carrier by a telephone push-to-talk key until the entire supervisory control function is completed. The conversation can be immediately resumed after the several seconds required to complete the supervisory control function.

The circuits for keying the carrier transmitters with the telephone push-to-talk keys are arranged so that it is only possible to transmit an impulse long enough to constitute a reset impulse for the supervisory control regardless of how short a period of time the push-to-talk key is operated. This makes it impossible to step the supervisory control from its normal at rest condition.

Conclusion

There are many installations of power-line carrier for supervisory control, telemetering, and communication services. In most of these installations a separate channel is used for each one of these services. In quite a number of cases carrier relaying has been combined with any of these three services on a single 2-terminal channel.[8] There also are installations of supervisory control combined with telemetering, and of supervisory control combined with communication on a 2-terminal channel. However, the installation described was the first in which a single-frequency channel was used for multistation supervisory control, telemetering and communication. This provides the most economical possible arrangement since a minimum of carrier equipment is required.

The fact that only a single-carrier frequency is required for this entire system is not particularly important in this instance, since no other carrier is in use on the Sierra Pacific Power Company system. However, this is an extremely important consideration in many sections of the country where it is becoming increasingly difficult to choose new frequencies due to the large number of channels already in use.

The carrier operated remote control installation described, has simplified system dispatching and improved system operation.

Discussion

C. E. Asbury and **C. W. Frederickson** (Commonwealth Associates, Inc., Jackson, Mich.): It is encouraging to see more functions being placed on one carrier channel and further efforts being made to conserve frequency spectrum. Multistation supervisory control on one single-frequency carrier channel should have its economic advantages. However it appears that the application of such a system may be rather limited. Multistation supervisory control over metallic circuits has been in general use for some time and apparently has given satisfactory operation. Multistation communication has also been successfully used for a number of years on single-frequency carrier current channels. It is significant to note that an additional step has been taken to place multistation supervisory control in service on the same carrier frequency which also provides multistation communication. It is hoped that the experience obtained from this application will be favorable and encourage further installations of a similar nature.

In an AIEE paper by R. C. Cheek and W. A. Derr,[1] the authors concluded that it was desirable to use separate channels for multistation simplex communication and supervisory control with joint use of cou-

plling equipment only. The reason given was the excessive amount of equipment and the complicated arrangement that would be necessary. It would be helpful if the authors would point out what changes have been incorporated in this design to simplify it, and hence remove their previous objection to the complicated arrangement.

Multistation equipment is generally applicable on smaller stations where it may not be objectionable to share the control of several stations on one set of dispatching equipment. On larger stations where a number of units are being controlled and supervised, it may be preferable to use one set of control equipment per station. This is often desirable to avoid losing control of all stations in the event the dispatching terminal of the control is out of working order or out of service for maintenance. The same objection is also true where numerous functions (supervisory control, telemetering, and communication) are used on one set of equipment. When the equipment is out of service all functions are inoperative.

The paper mentions that consideration was given to the use of telephone line wires, power line carrier, and microwave radio for the necessary interconnecting channels and that economic considerations led to the selection of power line carrier. Considering the short distance involved and the relatively high cost of the microwave equipment, it is apparent that microwave radio could not be economically justified. On the other hand it is not clear how carrier equipment could be less expensive than leased telephone channels on a system having such short distances between the dispatching point and the outlying stations. It may well be that the stations in question are remote from the present telephone lines in the area. In such a case it may be possible to justify the carrier system rather than resort to the construction of a private telephone channel. It would be interesting to know further details concerning availability, reliability, and rates of telephone channels in the area.

The paper states that no difficulty was experienced in receiving the carrier signal at the receiving stations. This would be expected since the lines are relatively short and all lines are trapped. About the only carrier loss experienced is that due to coupling and the coaxial cables. In applications where the transmission lines are longer and where the network consists of several lines this arrangement would be more difficult to apply since additional trapping would be required and the division of carrier signal between lines might be much less favorable. Sufficient carrier reserve signal should be available in applications of this nature to provide proper operation during adverse weather conditions such as fog, rain, or snow. To assure this reserve signal the carrier installation should be tested using an attenuator pad to determine the reserve range of signal over and above that required for operation during favorable weather conditions. It would be interesting to know if such a test was made in this particular installation, and if so, the decibel range of reserve signal found.

The basis of application of the line traps at the Washoe Hydro Station should be explained. According to Figure 1 of the paper there are six 60-kv lines emanating from this station with the carrier signal being applied to four of the lines. It would seem more practical and less expensive to trap the two lines which are not being used for carrier transmission rather than trap the four lines that are used. This would have the further advantage of not requiring a new trap when the proposed line is added out of Washoe for a fourth station also to be controlled by carrier.

The use of a double carrier channel between the Washoe Station and the Virginia City Substation appears rather difficult to justify. Considering that the line is only 18 miles long, the number of faults on the line per year should not be excessive. If the circuit is adequately protected the line should relay properly, and line damage sufficient to cause an interruption to the carrier channel, should not occur very often. It should further be noted that the only fault that would cause a complete interruption of the carrier channel would be one that would result in the wire being down on the particular phase being used for carrier transmission. A single channel would therefore seem to be adequate.

As stated in the paper, conservation of the frequency spectrum is of extreme importance in certain sections of the country. The use of a single-frequency channel for multistation supervisory control, selective telemetering, and communication is a means of accomplishing this. In many instances, continuous telemetering rather than selective telemetering is desired on a power system. In such a case the use of crystal controlled frequency shift telemetering channels permits the maximum possible number of continuous telemetering channels. This type of equipment has a much greater decibel range than the equipment mentioned in the paper. For this reason it can be used on systems where the telemetering channels have much greater attenuation than the channels listed in the paper. Since the maximum rate of impulse of the supervisory equipment (15 per second) is well within the allowable limits for a crystal controlled frequency shift channel, it would seem desirable to utilize crystal controlled channels for supervisory control. It is suggested that the authors state the possibility of such applications where communication is not required and give the equipment limitations, if there are any.

REFERENCE

1. THE COMBINATION OF SUPERVISORY CONTROL WITH OTHER FUNCTIONS ON POWER-LINE CARRIER CHANNELS, R. C. Cheek, W. A. Derr. *Electrical Engineering* (*AIEE Transactions*), volume 64, May 1945, pages 241–46.

P. W. Schirmer (General Electric Company, Philadelphia, Pa.): The authors have described in their paper what was to them a novel installation combining multistation supervisory control, telemetering, and communication over a single-frequency channel.

There has been such an installation in successful operation in New York State since June 1948. This installation consists of one control station with three outlying stations and includes supervisory control, communication, and selected telemetering over a single-frequency carrier channel.

There are a number of other installations having some of these features but designed to accommodate all if required. In the Midwest there is one installation including all these features, utilizing two relaying channels with a repeater between relaying channels providing the link for supervisory control, communication, and telemetering but still isolating the relay channels. This is not a single-frequency carrier channel over the entire system, but it is more economical as it employs the carrier terminals for a greater number of uses than described in the subject paper.

In conclusion, it should again be pointed out that the system described in the paper does not employ operating principles which are new to the art or which have not been employed previously. However, the authors should be congratulated for calling the public's attention to the rapid strides made in the art of supervisory control in the past few years.

W. A. Derr, T. C. Wren, and J. V. Kresser: We were very glad to receive the discussion of our paper prepared by Mr. Asbury and Mr. Frederickson.

The second paragraph of this discussion refers to statements made in a previous AIEE paper[1] concerning the combination of multistation supervisory control and communication. Note that this previous paper stated that multistation supervisory control should not be combined with a multistation simplex telephone system using separate ringing. However, it also stated that telephone ringing could be provided on a multistation supervisory control system; and this is the scheme used on the Sierra Pacific Power Company installation. Development work done since the previous paper was written in 1945 made it possible to omit the audio tone equipment.

There can be no argument with the statements made in the third paragraph of the discussion. The use of separate sets of equipment for large stations is definitely preferable when it can be economically justified.

With reference to paragraph 4 of the discussion, there are no telephone company lines between the Washoe Hydro Station and the stations controlled. A privately-owned telephone line was available but it was not considered a reliable channel, since it is often out of service during storms. The power line offered a much more reliable channel than the existing telephone line. The construction of a new telephone line of greater reliability was considered but the estimated costs for such a line were greater than the cost of the carrier equipment.

No tests were made to determine the decibel range of reserve signal. However, this equipment has been operated through a severe winter and adequate carrier signals have been obtained at all times.

The application of line traps at the Washoe Hydro Station is questioned in the sixth paragraph of the discussion by Mr. Asbury and Mr. Frederickson. Trapping of the lines to which the carrier is applied maintains more nearly constant characteristics of the carrier channel for all possible switching operations. When operation of a system is dependent on nearly equal division of carrier signals it is desirable to have switching operations change the channel characteristics as little as possible. The original installation offered no economic advantage for either method of trapping. There are

actually two more lines than are shown in Figure 1 at the Washoe Hydro Station.

The use of a double carrier channel between the Washoe Hydro Station and the Virginia City Substation was based on the experience of the Sierra Pacific Power Company with the two power lines. These lines, although only 22 miles long, go through very rugged terrain and are subject to severe storms during the winter. Past operating experience had indicated that permanent faults were to be expected on one or the other of the lines and sometimes on both lines. Quite frequently the lines are sectionalized at Reno Junction and Geiger Grade to locate the trouble. The alternative to the use of a double carrier channel would have been the use of carrier by-pass equipment at Reno Junction and Geiger Grade. Experience during the past winter has indicated that the use of the double carrier channel was justified.

Frequency shift carrier equipment can be used to provide for completely individual operation of each remote station but it cannot provide for telephone communication. It is to be noted, however, that a frequency shift transmitter and receiver are required at the controlling station as well as at the controlled station for each station controlled. Thus for the installation described, three transmitters and three receivers would have been required at the Washoe Hydro Station and no communication could have been possible. A separate frequency shift channel is required for each continuous telemetering indication or recording.

When frequency shift carrier is used for supervisory control operation, it should either be designed for d-c operation, or a battery operated a-c power supply unit should be provided so equipment is not made inoperative due to loss of station power.

It is unfortunate that Mr. Schirmer did not furnish more specific information on the installation mentioned in his discussion. It is impossible to compare this installation with the one described in our paper without such specific information. It is possible to combine functions on a single-frequency carrier channel without obtaining all of the desirable features which we have described in detail. For example, some designs might not give preference to supervisory control functions or they might necessitate the use of audio tone modulating equipment.

It is difficult to reconcile the statement by Mr. Schirmer about an installation made in 1948 with a statement made in 1949 by Mr. Forrest and Mr. Schirmer in an AIEE Paper.[2] The following sentence is quoted from this paper: "A separate additional metering channel is recommended for readings directly associated with a control function, or if a continuous reading of a selected quantity is desired."

In our paper we have described a particular supervisory control installation and we have not discussed the subject of combined functions on carrier channels in general. Where protective relaying is involved, it is of course possible in many instances to make use of consecutive relaying channels for supervisory control operation by providing repeaters between the relaying channels.

With reference to the last paragraph of Mr. Schirmer's discussion, we would like to point out reference 1 of this discussion which was published in 1945. That paper described the principles of multistation operation on a carrier channel. The principles having been thus previously discussed, it was our intention to describe an actual installation in detail and not to present entirely new principles. Our paper indicates the results of development work in recent years which has made it possible to improve the arrangement for the particular case of combined functions described.

Amplidyne-Controlled Log Carriage Drive

W. D. VINCENT
ASSOCIATE AIEE

Synopsis: The recently introduced amplidyne-controlled electric log carriage drive is rapidly becoming established in the lumber industry. This paper describes this new drive, explaining those features that make it a real asset to the lumber-mill owner.

FREQUENTLY the term "sawmill" is used loosely to refer to almost any lumber manufacturing plant; however, a more appropriate definition might be "an establishment that cuts planks, boards, and timbers, from logs." There are two general types of sawmills, the portable and the permanent type. The portable mill consists of the bare essential equipment required for cutting rough lumber, and it is transported from spot to spot for the purpose of sawing small tracts of available timber. The permanent type of sawmill, on the other hand, is a large factory-like structure with all of the necessary equipment for converting logs to a finished piece of lumber.

Generally speaking, portable-type sawmills will be found in nearly every section of the country, wherever small isolated tracts of usable timber are grown. However, the permanent-type sawmills will be found only in those areas still having large stands of timber. Most permanent-type sawmills own tracts of timber which have been set up on a perpetual yield basis.

After leaving the woods—either by rail, truck, or water—the logs are transferred to a log pond which is adjacent to the sawmill. From the log pond, the logs are moved into the sawmill either by a conveyor-type log haul or by a lift-type log hoist. Inside the mill the logs are cut to a length suitable for handling in the particular mill involved and are stored on a log deck.

The next step in the lumber-making process consists of cutting the logs lengthwise into long, thick planks and timbers. This is done by the headsaw, consisting of the saw itself, which may be either a circular or band saw, and the log carriage (a rail car upon which the log is supported). One plank after another is cut from the side of the log as long as the lumber is clear and high grade. When the saw begins cutting into the less salable heartwood, the log is rotated 90 or 180 degrees and higher grade planks are again cut. The sawyer in charge of the headsaw operation must decide the most profitable manner for cutting each log. It necessarily follows that the output from the headsaw determines the output of the entire mill. Thus, a leading sawmill must provide the sawyer with the most modern and effective headsaw equipment available.

Planks and timbers from the headsaw fall upon a live roll conveyor. This conveyor is the beginning of an elaborate conveyor system which separates various planks and timbers for proper processing through the mill. Some of the timbers have already been cut to usable dimensions by the headsaw and, hence, are carried directly to storage or shipping areas. However, the majority of the headsaw output must be cut and trimmed to produce rough lumber of standard dimensions. This is done by several different types of circular and band saws.

After the lumber has been cut to rough dimensions it is sorted by hand into groups of like grade and size. Then, the lumber must be thoroughly seasoned to prevent warpage and shrinkage. This is done either in dry kilns or by proper storage in the open air. After seasoning, the lumber may be shipped for use as rough lumber, or it may be processed through a planing mill where it is finished as required for use in lumber products.

Log Carriage

The log carriage for the headsaw consists of a steel or hard-wood framework of very heavy construction mounted on four to eight sets of wheels and riding on two or three steel rails. One of these rails is of V shape so as to keep the carriage on the track. Mounted upon the carriage is all of the necessary equipment for holding the log firmly in place and for accurately positioning the log so that desired thickness may be cut. The positioning and clamping equipment on the carriage may be actuated by levers, air cylinders, or motors, and one or more men ride the carriage for the purpose of manipulating these controls.

The sawyer in charge of all operations associated with the carriage, operates the carriage drive, moving it back and forth past the headsaw as desired. The man or men riding the carriage adjust the log for each cut according to instructions from the sawyer. A special sign language is used for conveying these instructions.

The track upon which the carriage rides must be approximately 20 feet longer than the longest log that will be cut.

Logs are loaded upon the carriage from a loading deck at one end of this track. Each time the sawyer desires to turn the log 90 or 180 degrees, the carriage is returned to this loading deck where a mechanical device (operated by the sawyer) flops the log over to the new position desired. Occasionally, the carriage must be run to the extreme opposite end of the track to facilitate the removal of a board by the "tail sawyer."

Paper 50-176, recommended by the AIEE General Industry Applications Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 13, 1950; made available for printing May 9, 1950.

W. D. VINCENT is with the General Electric Company, Schenectady, N. Y.

Figure 1. Diagram showing main components of the amplidyne-controlled log carriage drive

During the sawing of a log, the carriage is normally moved only far enough for the end of the log to clear the saw by about one foot. A very good sawyer will even reverse the carriage in the cutting direction before the trailing edge of the saw has cleared the log. The high production rate demanded can only be maintained if the sawyer is able to control precisely the point of the carriage reversal hundreds of times each hour.

The cutting speed of the carriage is adjusted by the sawyer and depends upon the dimensions, condition, and kind of wood being sawed. Normally, the return speed of the carriage is considerably higher than the cut speed in order to reduce the nonproductive time to a minimum. In some mills the carriage may reach a peak production rate of 15 round trips per minute, averaging nine or ten round trips per minute over an 8-hour shift.

Types of Carriage Drives in Use Today

In general, steam, air, hydraulic, and electric power have all been directly applied for the purpose of driving a sawmill log carriage. Until recently, the only types of drive considered by mill owners for high-production mills were the "steam shotgun" drive and the "steam twin-engine" drive. Compared to the steam drives, the hydraulic, air, and electric drives were all sluggish and incapable of producing the high output demanded by the leading sawmills. However, the recently developed amplidyne-controlled drive is now a serious competitor of the steam drives wherever high production, ease of control, and efficiency are demanded.

The Steam Shotgun. As its name implies, the steam shotgun resembles an actual shotgun both in appearance and performance. The shotgun feed consists of a cylinder up to 50 or 60 feet in length, depending upon the maximum length of log to be cut, made up in sections six or seven feet long and 10 to 16 inches in diameter. In this cylinder there is fitted a piston with a long rod which is attached to the carriage frame. The sawyer controls an operator's lever which by means of specially designed valves will admit steam in or out of either end of the piston, depending upon the direction of travel desired. Steam is admitted to either end of the piston at a pressure of approximately 125 pounds per square inch. The exhaust steam from the piston is generally considered as waste and is discharged into the atmosphere; however, in colder climates this steam is sometimes discharged into the log pond to prevent the formation of ice upon the pond in cold weather.

The Steam Twin-engine Drive. In many of the mills cutting the large fir timber grown on the Pacific Coast, twin-cylinder steam engines are used for driving the carriages. The engines are directly connected to a drum over which is wound several turns of steel cable, the two ends of which are attached to the two ends of the carriage. The twin engine essentially consists of a pair of steam engines with pistons operating upon a common crankshaft, so arranged with respect to each other that any dead spots, or zero-torque points are eliminated in the 360 degrees of travel of the crankshaft. This type of steam drive is more economical in steam consumption than the steam shotgun but also is more sluggish in performance, making acceleration and retardation rates lower and consequently reducing the daily output of the mill.

The Amplidyne-Controlled Log Carriage Drive

Components. The amplidyne-controlled drive *is* designed to achieve optimum performance utilizing the simplest possible combination of electric components. An idea of the simplicity of the electric drive may be gained from the following list of drive equipment:

1. Carriage driving motor
2. Motor-generator set
3. Amplidyne control panel
4. Operator's master control lever
5. Overtravel limit switches
6. A-c motor starters

A schematic diagram illustrating the arrangement of the principal drive components is shown in Figure 1. Carriage drives are available in ten different sizes as shown in Table I.

These mill-type motors (type *MDP*) are designed to operate successfully at more than double voltage and speed, thereby developing more than double of their nominal 230-volt capacity. Furthermore, they are designed to carry high peak loads encountered in steel mill and shovel work, making them exceptionally well suited for sawmill application.

The smaller drive sizes listed are usually applied to small sawmills or to pulp breakdown plants, whereas the larger drives meet all other production demands including the largest sawmills.

The Carriage Driving Motor. The carriage driving motor is a d-c motor built for extra heavy-duty service to withstand severe mechanical strains, high voltage, and large currents. The motor used is the same sturdy motor used so successfully in steel mills for auxiliary and crane service and in surface mining for driving excavation shovels. Heavy steel frames are split and the top half hinged for ease of inspection of the motor. Antifriction-type roller bearings are used for the armature which is also especially designed for low inertia and high-speed operation. Long-life brushes, extra large commutators, and high insulation levels provide extra overload capacity. The motor is completely protected and provided with high temperature rise, class *B* insulation with inorganic silicone-type binders, and the motor is separately forced ventilated with an integrally mounted blower motor to obtain the highest power capacity over the operating speed range of the motor, Figure 2.

Figure 2. Type-*MDP* blower-ventilated carriage drive motor mounted on a common base with gear reducer cable drum assembly

Figure 3. Log carriage drive motor-generator set

Type-*MDP* blower-ventilated generator on left, induction motor in middle, amplidyne and exciter at right (latest design omits blower unit on generator and reduces length of set by mounting amplidyne and exciter on top of generator)

Motor-generator Set. The 4-unit motor-generator set consists of an a-c driving motor, a d-c generator, an exciter, and an amplidyne,[1] see Figure 3. The a-c motor is specially designed with sufficient maximum torque available to meet the requirements of each particular drive and is normally a squirrel-cage induction motor.

The two smallest drives utilize specially designed type *CD* generators. All other drives use type-*MDP* units as generators which are duplicates of the drive motors with the exception of the omission of the blower units. Therefore, the generator is completely capable of supplying the current and voltage demanded by the motor and in the larger sizes the spare-parts problem is reduced to a minimum for these vital components of sawmill production. The exciter provides field excitation for the motor, and control power for the amplidyne control panel.

The amplidyne is similar in appearance to the exciter; however, internally it is so designed that this small piece of equipment becomes the heart of the amplidyne-controlled log carriage drive. In principle, the amplidyne is an externally driven d-c generator, but its unique use of a short circuit and compensating winding creates such precise electrical balance that the smallest electric signals release kilowatts of output capable of controlling the most powerful machinery. Essentially the amplidyne is a d-c amplifier with very high amplification[2]—more than 10,000 to 1—permitting the use of small control devices which are easy to manipulate.

The Amplidyne Control Panel. The control panel for a drive of this type is both simple and inexpensive, as are most amplidyne panels. Since it is controlling small amounts of current, the physical size of the panel is exceptionally small, Figure 4.

Control components consist of adjustable resistors, dry-type selenium rectifiers, electrolytic capacitors, and a small relay. This amplidyne control panel includes no regularly moving devices.

Operator's Master Control Lever. For the sawyer's operation, a simple heavy-duty drum-type master switch with a vertical handle is provided. By means of this master switch, the sawyer controls the direction and speed of carriage motion. Standing by the band saw and facing the carriage, the sawyer simply moves the master switch handle forward to bring the carriage into the cut and moves the master switch handle backward to return the carriage. The type of master switch offered has no points that can be felt by the sawyer and, therefore, the feel of the master switch is substantially the same as that of the steam control levers to which the sawyers have been accustomed over long years of usage. Figure 5 illustrates the simplicity and ruggedness of this control lever.

Safety Limit Switches. An overtravel limit switch is provided for overtravel protection on each end of the carriage travel. Thus, if the sawyer fails to reverse his master switch as the carriage approaches the end of the travel, the tripping of a limit switch takes control away from the master switch, applies a "suicide" connection to the amplidyne, and brings the carriage to a rapid safe emergency stop. Extra track length must be left between the limit switch and the end bumper so that sufficient distance is available for taking up the slack in the cable and decelerating the carriage to a stop as rapidly as the electric equipment will permit.

Figure 4. Amplidyne control panel for log carriage drive; approximate 28 inches high, 30 inches wide, and 9 inches deep

Table I. Carriage Drives—Nominal 230-Volt Motor Rating

Equipment Number	Carriage Motor	Hp	RPM	Generator Frame	M-G Set RPM	A-C Motor Hp
1	MDP602	9½	875	CD	1,800	30
2	MDP603	12½	775	CD	1,800	40
3	MDP604	19	700	MDP604	1,800	50
4	MDP606	31½	640	MDP606	1,800	100
5	MDP608	44	565	MDP608	1,200	100
6	MDP610	62½	540	MDP610	1,200	150
7	MDP612	94	510	MDP612	1,200	200
8	MDP614	125	475	MDP614	1,200	250
9	MDP616	187½	450	MDP616	1,200	400
10	MDP618	250	410	MDP618	1,200	500

Figure 5 (above). Sawyer's master control lever for log carriage drive; approximately 13 inches wide

Figure 6 (right). Simplified elementary diagram of amplidyne-controlled drive

A-C Motor Starters. Suitable a-c motor starters are provided for the motor-generator set driving motor and for each of the two ventilating blower motors.

Explanation of Operation. The amplidyne-controlled log carriage drive operates as a d-c adjustable voltage system. A heavy-duty d-c motor drives the carriage through a reduction gear and cable drum. Power for the motor is obtained from a 4-unit motor-generator set driven by an induction motor.

Basically, the operation of the system is quite simple. With fixed field excitation applied to the motor, the carriage speed is essentially proportional to the applied armature voltage. The armature voltage, supplied by the generator, may be changed by adjusting the generator field current. Therefore, the carriage speed increases as the generator field current is increased and decreases as the generator field is decreased. Also, the direction of carriage travel is reversed simply by reversing the current direction in the generator field.

The simplified elementary diagram for the amplidyne-controlled drive is shown in Figure 6. Field excitation for the generator is supplied by the amplidyne. The voltage output of the amplidyne is a function of the net ampere turns produced by the three amplidyne shunt fields. One of these fields is the reference field, the second is the current-limit field, and the third is the antihunt field.

When the sawyer moves his master control switch, essentially, he is changing the number of ampere turns contributed by the reference field. This results in a change in the amplidyne output voltage. Because of the field-forcing action of this reference field, the resulting change in generator voltage would be nearly instantaneous if it were not for the current-limit field. The limiting action of this field limits the maximum armature current in the motor and generator to a safe value. Thus, the resulting rate of armature voltage change (carriage speed change) is the maximum value that can be safely handled by the motor and generator. This current-limiting effect is obtained by comparing the voltage drop across the motor and generator commutating fields with a fixed reference voltage. When this voltage drop exceeds the fixed reference voltage, corrective ampere turns are produced in the current-limit field which correct the net amplidyne excitation to a value corresponding to safe armature current in the d-c driving units. A portion of the generator voltage is also impressed across the current-limit field. This voltage produces ampere turns in the current limit opposing the ampere turns in the reference field. Thus, when the sawyer's master switch is moved to a new position the generator voltage will continue to change until the balance point is reached between these two fields.

The antihunt field is connected in series with capacitors across the amplidyne output. Opposing ampere turns are contributed by this field only when there is a rate of change of amplidyne voltage. Therefore, the corrective action of this field is proportional to this rate of change and eliminates hunting, resulting from the combination of electric and mechanical time constants associated with the drive system. Overtravel limit switches, mounted near each end of the carriage track, will stop the carriage in emergencies. When either of the limit switches is closed, control of the amplidyne output is taken away from the reference field (master operator's switch), and the amplidyne output is suicided to zero through the current-limit field. This is done by applying a portion of the generator output to the current-limit field. The resulting ampere turns are always in the proper direction to reduce the generator voltage, while at the same time the current-limiting portion of the circuit is functioning to limit the maximum armature current.

Figure 7. View showing ease of operation of electric drive, demonstrated by sawyer as carriage nears end of last cut

A similar function to that of the limit switches is performed by the "off-position" suicide relay. When the master operator's lever remains in the off position, this relay sets up the suicide circuit which kills all generator voltage and eliminates carriage creepage. An extra interlock on the a-c motor starter for the motor-generator set is in series with this relay. Thus, if a-c power is lost in the mill, the carriage will be stopped before the saw is damaged.

Results

The first amplidyne-controlled electric log carriage drive was installed prior to the war in 1940.[3] Application of the drive was necessarily slowed down during the war years and subsequent drives were not installed until after the conclusion of the war. There are now installed and in operation a total of 11 of these drives. In addition, six more complete drives are under construction for installation in the near future, Figure 7.

Considering the relatively high initial price of an electric carriage drive and realizing that use of an electric drive is a departure from conventional sawmill practices, there must be some powerful arguments to justify the purchaser's expenditure of the extra money for an electric drive. Valid reasons do exist, and if a user can make the initial investment, he can hardly afford not to buy the electric drive.

For years, sawmill owners have thought of steam as being free power, since it is obtained by burning waste from sawmill operations. However, several factors are influencing a change in this viewpoint. Improved saws and sawing techniques are resulting in less waste. Waste utilization programs such as the manufacture of pulp, wood briquettes, wood flour, fibreboard, and alcohol, have placed a definite dollar value on sawmill waste. In addition, increased production requires more steam for kiln drying. Thus, the elimination of the notorious "steam hogs" of sawmills (the shotgun and twin-engine drives) results in appreciable dollar savings for mill owners.

The amplidyne-controlled drive consumes a comparatively small amount of energy. In each complete round trip of the log carriage, the carriage accelerates to a cutting speed, holds this cutting speed for a definite time, then decelerates to a stop, reverses and accelerates to a return speed, holds this return speed, then decelerates to a stop. The bulk of the power input to the system is required during the two accelerating periods of each cycle. In order to hold the carriage at a constant speed, it is only necessary for the system to supply the electrical and mechanical losses of the carriage and drive components. During the two deceleration periods of the cycle, the stored energy in the carriage motor and gear are converted back into electric energy and pumped back into the consumer's power system. Thus, it is obvious that the total power input required for each cycle is only that amount of power necessary to supply the electrical and mechanical losses in the system. On the other hand, steam-feed drives customarily waste all of their exhaust steam so that both the acceleration and deceleration require the maximum amount of power input from the steam source. Very careful analysis and calculations have been made of the energy consumption of both steam and electric drives, and the results turn out to be startlingly favorable for the electric drive. For example, it can be shown that the entire cost of an electric drive can be recovered in fuel savings alone, in four or five years.

Another striking attraction of the electric drive is the very low maintenance cost. Since there are no regularly moving parts in the control panel, maintenance there will be negligible. The master switch is a very simple device and should require very little attention. The rotating machinery, operating under favorable ambient conditions, should require only occasional maintenance in accordance with the general rules prescribed for that type of apparatus. Actual figures from one installation shows that $35.00 in a typical year covered the total maintenance cost including material and labor for the complete drive.

Safety of operating personnel is a matter of prime importance not only to the personnel involved, but to the management of the company. Assuming that the carriage was traveling at its maximum speed and for some unpredictable reason it was not stopped before reaching the end of the track, the personnel riding the carriage would be in very serious danger. Overtravel limit switches included as a feature of this drive minimize the possibility of this type of personnel injury.

Conclusions

Summarizing, the advantages of the amplidyne-controlled electric log carriage drive are as follows:

1. High drive efficiency resulting in low operating cost.
2. Low maintenance expenses.
3. Snappy acceleration and deceleration matching the performance of the steam shotgun.
4. Ease of operation reduces operator fatigue.
5. Definite speed control during sawing, resulting in improved quality of output.
6. Improved safety for operating personnel —automatic overtravel protection with emergency stop.
7. Automatic emergency stop when a-c power is lost, preventing possible damage to the saw.
8. Smooth nonpulsating cable pull, resulting in long cable life.

Discussion

H. A. Rose (Westinghouse Electric Corporation, Seattle, Wash.): Mr. Vincent is to be congratulated on his timely and valuable paper on electric log carriage drives. Increasing values assignable to sawmill waste and cost of operation of small steam plants are expected to show increased economic application of the electric drive. This will be particularly true for new and small capacity sawmills.

An important factor in the application of electric drives is the initial direct cost of equipment as compared to that for the steam engine and shotgun. The cost of electric equipment is approximately proportional to the horsepower rating required. This rating and cost for practical purposes is proportional to the total pounds weight (W) accelerated; the square of the maximum speed of the carriage in feet per minute (S^2), and inversely to the time required for acceleration in seconds (ΔT^{-1}). An analysis of these three factors will show that variations in cost by as much as 2-to-1 can be caused by casual specifications calling for performance characteristics not well matched to the actual needs of the particular application. This can easily result in the electric drive being discarded at the outset, when a more careful analysis of requirements would have proved it to be the most acceptable choice.

The importance of the weight factor (W) on cost of electric drives would seem to justify consideration on the part of log carriage builders to reduce weight by design and choice of higher strength materials. This appears particularly promising for the lighter weight lumber cutting carriages.

Mr. Vincent's paper describes a type of drive in which the cable drum is driven through a suitable speed reducer. This arrangement provides a very acceptable type of drive. My company however, in addition to building the "geared" type of drive manufacturers a "gearless" type in which a high-torque low-speed 2-bearing unit-type of armature and cable drum drives the carriage direct. On account of the simplicity and low maintenance of this type of drive, a number of applications have been made in ratings from 30 to 120 horsepower. Two units are presently on order.

W. D. Vincent: Selection of a suitable carriage feed should take into consideration an economic study as well as such nonmeasurable quantities as safety to personnel, ease of operation, and so forth. A complete economic study will, of course, include not only initial costs for all equipment but operating expense, maintenance costs, and replacement costs. Mr. Rose has stated that the rating and direct cost of electric equipment is approximately proportional to weight (W), maximum carriage speed squared (S^2) and inversely to accelerating time (ΔT^{-1}), or that rating and cost are proportional to $(W)(S)^2/(\Delta T)$. This is the familiar formula for the horsepower required to accelerate a weight to a definite speed in a given amount of time. Since the acceleration rate (A) is equal to the final speed (S) divided by accelerating time (ΔT), the foregoing formula may be rewritten as $(W)(A)(S)$. It is frequently more convenient to consider the formula in this form since it is thus readily apparent that for a specified carriage weight and maximum speed the acceleration rate is a direct measure of the power and performance of a drive.

It is common knowledge that both the "geared" and "gearless" types of electric drives are available for various industrial applications. Although, the gearless drive is somewhat simpler mechanically, the author believes the geared drive described in this paper has very definite advantages. The combination of the rugged, heavy duty, mill-type driving motor and the specially designed herringbone gear reduction unit has proved completely reliable for this application, with a negligible amount of maintenance being required. By choosing the optimum gear ratio for each application, the full motor power is available for any specified maximum return speed. Also, the motor designer can build a more powerful motor using less material at the higher speeds, and, for the ratings involved, considerably more horsepower per customer's dollar can be offered. Thus, the "geared" drive provides a faster acceleration rate (more snappy performance) for less cost.

Response Time of Magnetic Amplifiers

E. L. HARDER
FELLOW AIEE

W. F. HORTON
NONMEMBER AIEE

THE magnetic amplifier of modern design, while as much as a hundred times faster than its prewar cousin for the same gain, is nevertheless slower than an electronic amplifier, so that its response time is a vital factor in many of its applications. For example, in servomechanism design a representative time constant for the amplifier must be used. In on-off controls the time from application of the control signal until the output change is substantially complete is of importance. Or, speaking from a steady-state sinusoidal-signal point of view, the magnetic amplifier is a d-c amplifier and operates up to a signal frequency somewhat below its power-supply frequency. As the signal frequency approaches the power-supply frequency, the gain drops off rapidly. The magnetic amplifier is said to require a power-supply frequency "an order of magnitude" higher than the signal frequency.

Standardizing groups are now working on definitions and methods of expressing the performance characteristics of magnetic amplifiers, including response time. It is the purpose of this paper to present theoretical and experimental information on response time, to review the considerations involved, and to make some proposals for the treatment of response time in definitions and standards.

In order to discuss "time constant," it will be tentatively defined as the time for completion of 63 per cent of an output voltage change after a step change in input voltage, in some specified region in which output and input bear a reasonably linear relationship. The further details and qualifications must await the development of the text. The term "response time" will be used in a more general sense to denote the time to respond to any specified degree after a step change of input.

Operation of the reactors of a magnetic amplifier into the saturated region does not in itself preclude a constant "time constant." The time constants of magnetic amplifiers are at least as constant as those of many machines and other devices which are so treated in servomechanism and closed-cycle control system analysis. In fact, the extreme assumption of a 2-straight-line saturation curve, with its very abrupt saturation, results in theoretically constant "time constants" for two important cases. The saturation curve composed of a vertical and horizontal line results in a theoretically constant "time constant" for the simple series-connected amplifier with low control resistance. The saturation curve composed of an almost vertical line and a horizontal line results in a theoretically constant "time constant" for the self-saturating amplifier. Deviations from constancy are thus not caused by the main bend of the saturation curve but by minor effects in some of the more important amplifier circuits.

Since the modes of operation of various magnetic amplifier circuits do vary considerably, with consequent effect on the response time considerations, the theoretical aspects of a number of the common connections will first be reviewed as briefly as possible. The series and parallel connections with and without external feedback and the self-saturating circuit will be treated. These, it is believed, will introduce practically all of the principal considerations involved in the response time of magnetic amplifiers. Because of its importance and, curiously, because of its simplicity, the self-saturating circuit will be considered first. The steady-state operation is well known and will be only briefly stated as a foundation on which to build concepts of transient operation.

Paper 50-177, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 15, 1950; made available for printing May 12, 1950.

E. L. HARDER and W. F. HORTON are with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Concepts of Response Time

THE SELF-SATURATING MAGNETIC AMPLIFIER

Steady-State Operation. Operation of the self-saturated amplifier of Figure 2 is as follows. At the beginning of a forward half cycle of supply voltage, in the diode conducting direction, for reactor *1*, let the flux in that reactor have the initial value shown at *a*. The conditions of signal current and other factors that determine this initial flux will be discussed shortly, but for the time being *a* is simply some point on the upper branch of the major hysteresis loop. When forward voltage is applied, the flux, ϕ, rises to saturation, along the line *ab*. For simplicity it will be assumed that the magnetomotive forces below saturation involve currents so low that they cause negligible drop in the load resistance. The entire applied voltage is taken up across reactor *1* until saturation is reached. The flux in rising from *a* to saturation generates a back voltage equal to the applied voltage, this flux change being used up in generating a definite volt-time area. Thus after a voltage area has been generated proportional to the initial flux reduction (saturation flux minus initial flux), the reactor saturates and from this time until the end of the half cycle, voltage is taken up across the load resistor. Thus a linear relation exists between the initial flux reduction in the reactor and the voltage-time area absorbed by the reactor during this half cycle. That is, the average voltage on the load resistor is reduced from its maximum possible value by an amount proportional to the initial flux reduction. The resulting voltage on the load is shown in Figure 2 as e_L. Note that during the next half cycle a similar action occurs in the other reactor while the first returns to its initial flux position.

With a smaller initial flux reduction, when the forward voltage wave is ap-

plied, the flux follows a path such as $a'b'$ and saturation is reached sooner. Thus a smaller area is cut out of the voltage wave proportional to the smaller initial flux reduction, and the larger load voltage e_L' results.

With a greater initial flux reduction the flux follows a path such as $a''b''$. A correspondingly large area is cut out of the voltage wave and a small load voltage e_L'' results. Since the load is resistance, the load current is proportional to the load voltage and of the same wave shape.

Summarizing, in the idealized case, the average load voltage is reduced below a theoretical maximum equal to the full applied voltage by an amount directly proportional to the initial flux reduction. Note that signal current in the forward direction reduces the initial flux reduction (increases the presaturation) and hence increases the load voltage and current. Signal current in the reverse or negative direction increases the initial flux reduction, enabling the reactor to absorb more voltage and correspondingly lowering the load voltage.

This direct proportionality between a change in the initial flux reduction and the change in average output voltage of the self-saturated magnetic amplifier is a basic tenet in much of the discussion of response time that is to follow. It need only be pointed out at this time that since the saturation flux density is fixed, the average flux, that is, the mean of the initial flux and saturation flux, changes by half of any change of initial flux. Changes in average flux, initial flux, and average load voltage are all proportional to each other and are found to appear rather indiscriminately in the response time formulas set forth by different authors. It is, of course, the average flux that, linking the control windings, opposes the change of average control current and determines the time constant. In fact, in the L/R ratio comprising time constant the R is the parallel of all the control winding resistances on a common turns base. The L corresponds to half the slope of the upper branch of the major hysteresis loop between the two initial flux points of interest. These facts will be developed more fully in the course of the paper.

If the initial flux is lowered somewhat below point a'' in Figure 2, the core remains unsaturated throughout the full cycle and only the small unsaturated magnetizing current flows. If lowered further to a''', the current flows in each reactor throughout nearly 360 degrees, with pulses of load current at the end of each half cycle. This mode of operation is entirely different from that just discussed and cannot be analyzed on the basis of the half-wave circuit.

Figure 1. Magnetic amplifier

A typical transfer curve for such an amplifier showing operation in these two regions is given in Figure 3, with the operating points a', a, a'', a''' indicated. Note the lower gain (lower slope) in the negative slope region of high negative control. In the positive slope region of the transfer curve control is obtained by the very minute amount of current required to obtain different initial flux reductions on the upper branch of the major hysteresis loop.

Typical wave forms of an actual amplifier are given in Figure 4. The general characteristics of the shapes shown in Figure 2 will be observed although the changes are less abrupt because of the more gradual saturation. Also the unsaturated magnetizing current is not negligible.

Transient Response. Transients in magnetic amplifier circuits are normally treated as slow transients, that is, as a progression through various steady-state operating conditions from one limit of the change to the other. The quantities dealt with, then, are the average applied control voltage, the average flux linkage, and the average output voltage, averages being taken over a cycle. Such treatment is quite satisfactory for transients of several cycles duration.

Transients of short duration become much more complex and depend on many factors which can be safely ignored in the longer transient. For example, in the amplifier just analyzed there is a part of the cycle in which no current flows in the load. A change in control voltage during this interval could obviously have no immediate effect on the load. Thus, very short transients must depend on the point of the cycle at which they are initiated. It is only the so called slow transients involving average quantities that are of much significance and these are the ones that will be treated here. Departures therefrom will be shown experimentally.

The problem of determination of the time constant,[3] $T=2L_s/R_s$, is mainly one of determining the average flux linkages per core per ampere of signal current that constitutes the quantity, L_s. Refer to

Figure 2. The resistance, R_s, is the total signal circuit resistance, L_s is the effective inductance per core.

Or, noting that

$$T=\frac{2L_s}{R_s}=\frac{2\,\Delta\psi_{s\,ave}}{R_s\Delta I_s}=\frac{2\,\Delta\psi_{s\,ave}}{\Delta E_s}\text{ seconds} \qquad (1)$$

where $\Delta\psi_{s\,ave}$ is the average flux linkages per core with the signal winding, the time constant of interest can be determined directly as the ratio of change in average flux linkages to change in signal voltage.

As pointed out previously, for the idealized case of sharp saturation, changes in average flux (hence flux linkages) and average output voltage are proportional. The relation is

$$2\,\Delta\psi_{s\,ave}=\Delta E_L\frac{N_s}{N_L}\frac{1}{2f} \qquad (2)$$

Making this substitution in equation 1

$$T=\frac{\Delta E_L}{\Delta E_s}\frac{N_s}{N_L}\frac{1}{2f}\text{ seconds} \qquad (3)$$

or

$$T=\frac{Av}{2f}\text{ seconds} \qquad (4)$$

where Av is the average voltage gain on a common turns base

$$Av=\frac{\Delta E_L}{\Delta E_s}\frac{N_s}{N_L} \qquad (5)$$

Equation 4 gives a low value as the saturation curve deviates from a flat top, since it is based on a change in average flux only half of the change in flux swing, which generates voltage drop. Using some data from Johnson and Latson[4] for a silicon steel reactor of very gradual saturation

$R_s=139$ ohms
$N_s=4000$ turns
$\Delta I_L=4.0$ amperes (from 4 to 8)
$\Delta I_s=0.02$ amperes approximately

Figure 2. Operation of a self-saturated magnetic amplifier

Figure 3. Transfer curve of a typical self-saturated magnetic amplifier

$R_L = 10$ ohms
$N_L = 230$ turns
$\Delta E_L = 40$ volts
$\Delta E_s = 2.78$ volts

$$Av = \frac{\Delta E_L}{\Delta E_s}\frac{N_s}{N_L} = \frac{40}{2.78} \times \frac{4000}{230} = 250$$

$$T = \frac{Av}{2f} = \frac{250}{120} = 2.1 \text{ seconds}$$

The measured value in this region was 3.3 seconds. The value by a more accurate calculation according to equation 1 was 3.7 seconds.

Figure of Merit. Since the time constant is determined as the flux linkages per unit of signal voltage, doubling the signal-circuit resistance will double the voltage required for the same linkages and hence halve the time constant. Also, since twice the signal power (change) is now required for the same output power (change), the power gain A is also halved.

This proportionality between A and T as the signal-circuit resistance is varied is illustrated in Figure 5. It has led to the suggestion of using the ratio A/T as a figure of merit for comparing amplifiers of the same size and type. For operation in a specified region, it would show up in a single figure the beneficial effects of high-permeability iron, low-leakage rectifiers, and quality of design in respect to space utilization in lowering internal resistance, leakage resistance, and so on. It would also afford a more universal constant to associate with amplifiers of various types.

The difficulties lie in adequately specifying all the conditions of test and the inexact nature of the ratio. Note that in Figure 5, A is not exactly proportional to T. In other amplifiers this deviation is considerably greater than shown.

Also note that as the time constant approaches one cycle of the supply frequency, the ratio drops off quite rapidly as the long-transient theory applies less accurately and the lamination and a-c winding delays become a factor. Not shown in this figure are differences in increasing and decreasing transients. If the voltage induced in the a-c windings by the applied signal voltage exceed the back voltage on the one diode, a circulating current can flow for decreasing transients, thereby slowing the response. This does not occur for increasing transients since the induced voltages are counter to the diode conducting directions. Thus, figure of merit will probably remain a useful though inexact amplifier constant which will not receive industry standardization until its limitations have been more thoroughly explored in the various circuits.

Johnson and Latson Method.[4] The complete method described by Johnson and Latson using the generalized curves of an earlier paper[4] involves dead reckoning from the a-c saturation curve, the winding and load resistances, and the turns, to the final performance. The proper set of universal performance curves are picked corresponding to the master saturation curve that best matches the one under consideration. These curves show the average flux linkages for each operating point as well as giving necessary data for the transfer curve (output versus input). Thus, equation 1 above can be used directly since no approximation for flux linkages is needed.

Having plotted the transfer or control characteristic, giving the load current versus control current without feedback, the reduced signal current for any desired percentage of feedback is readily determined, and likewise the signal voltage. For a given operating condition, with feedback, including self-saturation or 100 per cent feedback (50 per cent in their terms), the average flux linkages are determined from the universal curve, the signal voltage determined as explained, and the time constant thereby calculated by equation 1.

For the silicon-steel reactor mentioned, the calculated time constants agreed with experimental values within 10 to 17 per cent (calculations uniformly high) for 73 per cent external feedback, and agreed within 12 per cent (3.7 seconds calculated, 3.3 seconds test) for the self-saturated circuit. Checks were not available for high-permeability materials.

Frequency Response Versus Time Constant

Representation of the magnetic amplifier as a single delay system may be tested by comparing its frequency response with that of a theoretical single delay. Such a comparison is given in Figure 6(B). Note that the theoretical curve for the single delay drops off in voltage response to 50 per cent (voltage) at a signal frequency of 2.55 cycles per second for the test amplifier which has a time constant of 6.5 cycles, measured with a step function. The test amplifier follows the theoretical curve reasonably well, indicating that representation as a single delay is justified.

Table I shows the theoretical possibilities of passing various frequencies. To obtain 87 per cent voltage response (75 per cent power response), even with a 2-cycle time constant, which is about the lower limit of linearity between A and T, the signal frequency must not be over 4.6 per cent of the supply frequency, that is, three cycles per second for a 60-cycle supply. Fifty-per cent power could be obtained at eight per cent or approximately five cycles per second, with 25-per cent power at 13.8 per cent or eight cycles per second. Below this point, power varies inversely as signal frequency squared, or voltage inversely as the signal

Table I. Response of Single Delay System

Output*/Input Voltage or Current, Per Cent	Power, Per Cent	fT**	Signal Frequency/Supply Frequency for Amplifier Time Constants in Cycles of Supply Frequency: 1 cycle	2 cycles	5 cycles	10 cycles
86.6	75	0.092	0.092	0.046	0.019	0.009
70.7	50	0.160	0.160	0.080	0.032	0.016
50	25	0.276	0.276	0.138	0.055	0.028
10	1	1.60	1.60	0.80	0.32	0.16

*Based on 100 per cent for d-c signal.

**$\frac{f}{f_o}$ = signal frequency/supply frequency.

T = time constant in cycles of supply frequency.

frequency. That is, they drop off at six decibels per octave. Thus serious attenuation is encountered unless the supply frequency is at least ten times the signal frequency.

The profit from lowering time constant by increasing signal-circuit resistance is now evident. If the amplifier is putting out 50-per cent power (in terms of that with a d-c signal) at the frequency of interest, a reduction of the time constant to half could not possibly reduce attenuation to half (double the gain), whereas a two-to-one loss in gain (at least) would be suffered in the increased resistance. Below the 25-per cent power, reducing time constant reduces attenuation (raises gain) as the square at the cost of only a first-power loss in the signal-circuit resistances. Obviously some place in between there is an optimum product of d-c gain $\times \frac{\text{gain at signal frequency}}{\text{gain at d-c}}$. Such an optimum amplification occurs at $1=(1/2\pi T)(f_o/f)$ or $(f/f_o)T=0.159$.

Response Time of Small Self-Saturated Magnetic Amplifiers

Practical Considerations. Consider self-saturating amplifiers in the 0–50-watt class, having several control windings and using gapless cores of high-quality magnetic-amplifier steel such as Orthonol, Hipernik V, or others. The practical response time considerations are then as follows.

The natural response time with zero external resistance is of the order of 3–6 cycles if built for moderate gain, up to 30–60 cycles if built for high gain. The delay in output response after a step change of input is occasioned chiefly by the L/R of the control winding, with 1/2 to 2 cycles added delay in laminations and a-c windings.

A typical transfer curve for such an amplifier is given in Figure 3. In general, if response is measured for a step change that runs the output from one end to the other of the high-gain region or some smaller part of it, the response times for 63 per cent or 95 per cent of full response will be nearly independent of the magnitude of change and hence nearly constant. The 63-per cent value can be used as the time constant in control-system calculations with accuracy equivalent to that with small machines and many other devices which also involve some deviations from true time constants. The 95-per cent value is approximately three time constants.

In this case the several control windings, signal, bias, feedback, and so on, may be considered as substantially 100 per cent coupled together and so act as though having a single control time constant, T_c, which is the sum of their several individual time constants considered separately

$$T_c = T_s + T_b + T_f + \ldots\ldots \tag{6}$$

To this combined control-winding time constant must be added one-half to two cycles of lamination and a-c winding delay to obtain the effective over-all time constant of the amplifiers. The individual control-winding time constants may include external resistance but not external inductance if the 100-per cent coupling premise of this simple treatment is to be fulfilled.

Time constant is frequently controlled by using high resistances in the bias and feedback windings, if not open-circuited making T_b and T_f very small. Then T_c is substantially equal to T_s and can be reduced to the desired value by introducing series resistance in the signal winding, at the cost of correspondingly reduced gain.

It may be noted that the control time constant is proportional to the sum of the turns squared per ohm of the several control windings. That is

$$T_c = \frac{L_s}{R_s} + \frac{L_b}{R_b} + \frac{L_f}{R_f} + \ldots\ldots \tag{7}$$

whence

Figure 4 (below). Wave form of load voltage and current for a typical self-saturated amplifier with resistance load

Toroidal Hipernik cores are used

Figure 5 (right). Effect of adding resistance in the control circuit of a magnetic amplifier

Figure 6. Frequency response of a typical magnetic amplifier

A. Oscillograms. B. Plot of response versus frequency and comparison with an ideal single delay system. Curve calculated from experimental time constant of 6.5 cycles at 60 cycles

$$T_e = P\left(\frac{N_a^2}{R_a} + \frac{N_b^2}{R_b} + \frac{N_f^2}{R_f} + \ldots\ldots\right) \qquad (8)$$

where P is the permeance of the common magnetic circuit.

Hence the response times of a magnetic amplifier can be measured using any combination of control windings and plotted as universal curves as a function of the quantity in parenthesis which has the dimensions of turns squared per ohm. It has also been plotted as a function of the reciprocal of this quantity, that is, ohms per turn squared. In the latter case

Ohms per turn squared =

$$\frac{1}{\dfrac{N_a^2}{R_a} + \dfrac{N_b^2}{R_b} + \dfrac{N_f^2}{R_f} + \ldots\ldots} \qquad (9)$$

Thus the plot of response time versus ohms per turn squared can be readily interpreted to give the response times for any combination of control windings and external resistances.

It may be well to point out the correlation between the concept of adding time constants of circuits 100 per cent coupled, and the computing of a single time constant using the common inductance and the parallel of the several resistances expressed on a common turns base. These are in reality the same concept as can be seen from the equivalent circuit of Figure 7. Since there is but one inductance, there can be but one mode, expressed by a single time constant. As shown in the figure it is the sum of the individual time constants.

It can also be shown that the ratio of amplification to time constant is independent of the turns of the control winding used, assuming that the sum of feedback and bias time constants is not changed. For example, in a magnetic amplifier having three control windings of different numbers of turns, only one of which is to be used, then regardless of which is used, when sufficient external resistance is introduced to achieve the same time constant, the same gain will also exist.

The further addition of bias and feedback will have the same effect regardless of which winding is used in each position, provided only that the per cent feedback is the same and the sum of the time constants is the same. These relations follow from the fact that the response time is a function of control ohms per turn squared, and amplification is a function of ampere turns secured per unit of power input. When a given control ohms per turn squared is secured in any manner whatever, the time constant is fixed. Also, when a given signal winding ohms per turns squared is secured, the application of given ampere turns (hence fixed output) will result in a fixed signal (ampere turns squared).

These fixed ampere turns squared in a fixed ohms per turn squared result in a fixed ampere squared ohms (I^2R) or power input, hence a fixed amplification. Thus it is seen that fixing total control ohms per turn squared, the signal ohms per turn squared and per cent feedback, fixes the response time and gain.

The Series-Connected Magnetic Amplifier with Low Control Resistance

Steady-State Operation. Consider the magnetic amplifier of Figure 8(A), under the following assumptions:

1. Square saturation curve with no hysteresis, as shown in Figure 8(B).
2. Leakage reactances negligible.
3. Control circuit resistance very small compared with load resistance when expressed on same turns base.

The end of each voltage wave finds one reactor completely saturated and the other at some value of flux ϕ_1. Current reaches zero at the voltage zero. This

will become clear later and the reader is asked to accept this starting point.

As the voltage reverses one flux starts downward from saturation and the other upward from ϕ_1. Both reactors are unsaturated and each takes up half of the applied voltage. No current flows until the flux in one reactor has risen from ϕ_1 to saturation flux ϕ_s. As it saturates, it presents a zero impedance on both its output and control windings and thus effectively short-circuits the other reactor as well.

From this time on, the full applied voltage is across the load so that the load current is a part of a sine wave of value e/R_L. As one reactor is unsaturated, it must have equal ampere turns on output and control windings and thus load and control currents are equal at every instant (when expressed on the same turns base). The half cycle ends with current zero at voltage zero and the other reactor having the flux ϕ_1. Note several interesting facts:

1. Since the flux rises in one reactor at the same rate that it falls in the other, the total flux linking the control circuit is constant under steady load. It is $\phi_s+\phi_1$ or if the maximum flux dip below saturation is called ϕ_m it is $2\phi_s-\phi_m$. This is the flux that determines time constant. ϕ_s is constant but ϕ_m will vary with the load.

2. The average load winding voltage is proportional to the flux swing, ϕ_m.

3. The control current I_c must have the average value E_c/R_c. But it must also have the same average value as the load currents (on the same turns base). The firing angle at which a reactor saturates and load current starts to flow adjusts itself until the average load current is equal to the average control current, E_c/R_c.

4. If the load resistance is changed, the firing angle will readjust until the average load current is again equal to the average control current. Thus for a given control current the load average voltage varies directly with the load resistance.

Transient Operation. Thus, in this case, changes in load resistance, load average voltage, and control flux linkage are all proportional, and the time constant is[1]

$$T=\frac{1}{4f}\frac{R_L}{R_c'}\text{ seconds} \tag{10}$$

where R_c' is the control circuit resistance on the output winding turns base

$$R_c'=R_c\frac{N_L^2}{N_c^2} \tag{11}$$

These results hold in the proportional range where the currents are well above unsaturated exciting currents, and hence proportional, but yet are below an average load current of E/R_L, the limit of what

Figure 7. Equivalent circuit of several 100-per cent coupled windings showing that the time constant of the equivalent circuit is the sum of the time constants of the coupled circuits

$$T_s=\frac{L_s}{R_s'},\quad T_b=\frac{L_b}{R_b'},\quad T_f=\frac{L_f}{R_f}$$

$$L=\frac{L_s}{N_s^2}=\frac{L_b}{N_b^2}=\frac{L_f}{N_f^2}$$

$$T_c=\frac{L}{R}=\frac{L}{\dfrac{1}{\dfrac{N_s^2}{R_s}+\dfrac{N_b^2}{R_b}+\dfrac{N_f^2}{R_f}}}$$

$$T_c=T_s+T_b+T_f$$

$$=\frac{L_s}{R_s}+\frac{L_b}{R_b}+\frac{L_f}{R_f}$$

$$=\frac{L}{\dfrac{R_s}{N_s^2}}+\frac{L}{\dfrac{R_b}{N_b^2}}+\frac{L}{\dfrac{R_f}{N_f^2}}$$

$$T_c=\frac{L}{\dfrac{1}{\dfrac{N_s^2}{R_s}+\dfrac{N_b^2}{R_b}+\dfrac{N_f^2}{R_f}}}$$

could be supplied by the given supply voltage.

Since the currents are equal, on a common turns base the resistance ratio is the same as the average voltage gain.

$$\frac{R_L}{R_c'}=Av \tag{12}$$

So that the time constant can also be written as

$$T=\frac{Av}{4f} \tag{13}$$

which is reminiscent of a similar expression for the self-saturated amplifier, equation 4, $T=\dfrac{Av}{2f}$

In the derivation of equation 10, and hence of 13, use is made of assumption 3 (see foregoing section on "Steady-State Operation") that R_c' is very small compared with R_L. Hence any large increase in R_c' to lower T, invalidates the formulas.

Amplification and Transfer Functions.[1] For the previous circuit the voltage gain is

$$K_e=\frac{R_L}{R_c'}\frac{N_L}{N_c} \tag{14}$$

and the voltage transfer function is therefore

$$K_eG(p)=\frac{R_L}{R_c'}\frac{N_L}{N_c}\frac{1}{1+pT} \tag{15}$$

where T is defined in equation 13.

The power gain is

$$K_p=\frac{R_L}{R_c'}k_f^2 \tag{16}$$

where k_f is the form factor and varies from 1.1 for the sine wave maximum currents to approximately 1.5 for the highly distorted minimum currents. As k_f may not be constant throughout the change, there is not strictly a time "constant" for power, although it is nearly a constant for small changes.

The corresponding transfer function is

$$K_pG(p)=\frac{R_L}{R_c'}k_f^2\frac{1}{1+pT} \tag{17}$$

Such an amplifier has an absolute maximum current, which can be delivered with reactors completely saturated, of

$$I_{LM}=\frac{E}{R_L} \tag{18}$$

Storm[1] points out that the time constant as derived in the foregoing applies for any change in the amplifier conditions of operation. Transfer functions for other possibilities are as follows:

For a change in line voltage

$$\Delta I_L=\frac{\Delta E}{R_L}\frac{pT}{1+pT} \tag{19}$$

$$\Delta I_c=\frac{\Delta E}{R_L}\frac{N_L}{N_c}\frac{pT}{1+pT} \tag{20}$$

Note that these involve no sustained changes.

For a change in load resistance R_L to R_L' at $t=0$

$$\Delta I_L=I_L\left(\frac{R_L-R_L'}{R_L}\right)e^{-\frac{t}{T}} \tag{21}$$

That is, there is a sudden current increment that keeps the load voltage constant and this dies out with a time constant T computed from the changed load resistance R_L'.

Series-Connected Amplifiers with High Control Impedance, or Current Transductors

In the current transductor, the control current is fixed entirely by the control

Figure 8 (left)

B. Idealized saturation curve

Figure 10 (right). Amplification versus time delay relationships as control resistance is varied

Hipernik V toroidal cores and 440-cycle supply are used

circuit, which may be a high-current d-c bus, for example. In steady operation one reactor is saturated and one unsaturated at all times. Thus on one current half cycle one reactor forces the output ampere turns to equal the control ampere turns, the other reactor being completely saturated. On the next current half cycle, the other reactor forces the equal-ampere-turn relation.

If a control-current change were to occur, the active reactor, at the moment, would continue to force the equal-ampere-turn relationship. Thus the transient response is practically instantaneous.

Parallel-Connected Amplifier

Approximate Time Constant. An approximate expression has been given[2] for the time constant of a parallel-connected magnetic amplifier without self-saturation based on the average reactance in the region of interest. Referring to Figure 9(A), the saturable reactor is assumed to be biased for operation at point *O*. An average reactance is determined, which is

$$X_o = \frac{V_{ao}}{I_{Ao}} \tag{22}$$

From this an effective permeance of the core is determined, since

$$X_o = 2\pi f N_A^2 P_o \tag{23}$$

$$P_o = \frac{X_o}{2\pi f N_A^2} \tag{24}$$

The control coil inductance, using the same permeance, is then

$$L_c = N_c^2 P_o = \frac{N_c^2}{N_A^2}\frac{X_o}{2\pi f} \tag{25}$$

and the time constant is therefore

$$T_o = \frac{L_c}{R_c} = \frac{X_o}{2\pi f R_c}\frac{N_c^2}{N_A^2} \tag{26}$$

Time constants computed according to this formula agreed with tests on a sample amplifier within ±15 per cent. The

reactor tested was a 3-legged reactor of silicon steel having gradual saturation characteristics.

Similar Operation of Series and Parallel Connections. Several authors[4,6] have shown that the parallel-connected amplifier, steady-state operating mode, is identical with the series-connected amplifier with low control resistance. Either provides a circulating path for the even harmonics. That is, when due account is taken of doubling the voltage, halving the current, and quadrupling the load resistance for the series connection as compared with the parallel connection, the steady operation and hence the control-winding flux linkage is the same.

A difference is encountered, however, in the coupled circuit in the case of the parallel connection, which effectively increases the time constant as discussed earlier for coupled control circuits. The time constant, as compared with the series connection, is increased by the ratio of control circuit resistance to the parallel of control and a-c resistances (loop through two a-c coils) expressed on the same turns base.

Let

$$R_{ac}' = R_{ac}\frac{N_c^2}{N_{ac}^2} \tag{27}$$

This ratio is then

$$\frac{R_s}{\dfrac{R_s R_{ac}'}{R_s + R_{ac}'}} = \frac{R_s + R_{ac}'}{R_{ac}} \tag{28}$$

The time constant is

Figure 11. Before-saturation delay of a series-connected magnetic amplifier with several magnitudes of supply voltage but the same step signal voltage, starting from zero signal, with no feedback or bias

$$T = \frac{L_s}{\dfrac{R_s R_{ac}'}{R_s + R_{ac}'}} \tag{29}$$

and approaches L_s/R_{ac}' as a limit as R_s is increased.

This effect is illustrated in Figure 10 in which the performance of the self-saturating circuit with increasing control resistance is compared with a parallel-connected amplifier with external feedback. The A-versus-T relation is the same at low control resistance, but at higher values the parallel-connected amplifier reaches a lower limit of time constant as outlined in the foregoing.

Note also that if time constant is reduced by lowering the percentage feedback, the gain drops off as the square instead of the first power of the time constant. This illustrates the point, now well known, that higher speed for the same gain can be obtained with feedback than without, through the use of control-circuit resistance.

Before Saturation Delay

A concept of response time utilized since the early days of saturable reactors is of interest here in that it represents another aspect of the problem. The circuits considered were the series and parallel circuits without self-saturation, Figures 8 and 9. When control voltage was applied, there was a lapse of time before it seemed to take effect, after which the load current rose rapidly throughout its range to maximum. This time lapse was observed to be twice as long with the parallel circuit as with the series circuit.

The explanation of this phenomenon and the resulting concept of response time is as follows. The most common reactors were in the several hundred watt size used for theater light dimming and other load applications requiring liberal proportioning of iron and turns so as to control down to low reactor exciting currents. Thus the reactors operated at only 10,000 or 12,000 gausses when absorbing the full line voltage at zero control. With the ordinary silicon steels in use up to 1935, the saturation density was about 20,000 gausses.

With no self-saturation, the reactor a-c and d-c ampere turns were equal and amplification resulted simply from the lower direct voltage required as compared with the alternating voltage controlled. Suppose this ratio of direct voltage per core required for full control to average alternating voltage per core was 1/50 on the same turns base. Since a half cycle of the alternating voltage caused a flux change of twice full flux, it would require 50 half cycles of the direct voltage to cause this much change. Thus a large number of cycles were involved until the mean flux had been shifted to the point that the peaks of the a-c flux wave were dipping appreciably into the saturated region. From this point on the mean inductance dropped rapidly, the direct current rose quickly to the E/R value, and the alternating current to the corresponding value.

That the time lapse is twice as long with the parallel connection is explained by the use of approximately equal space for a-c and d-c windings in this type of amplifier. This makes the a-c and d-c winding resistances nearly equal on the same turns base. Thus, as shown in the equivalent circuit, Figure 9(B), only half of the applied voltage appears on the magnetizing branch, so that it requires twice as long to reach saturation.

The development of improved steels such as Hipersil has made possible working much closer to the saturation flux density even with large power size reactors with control to low currents. However, the delay in the relatively unsaturated region is still an important factor. Frequently it involves sacrifice of range or increased size to permit use of sufficient bias to keep partial saturation and avoid excessive delays. For example, in a 200-kva ±10 per cent regulator for a 2,000-kva load, this factor required special consideration. Consequently some provision must be made in nomenclature for description of this before-saturation delay in larger sizes of magnetic amplifiers.

This phenomenon is illustrated in Figure 11, which shows the before-saturation delay for various magnitudes of a-c supply voltage with the same load resistance, for a pair of silicon steel reactors of approximately 200-watt rating.

Conclusions and Recommendations

In view of the considerations set forth in the paper, the following conclusions seem justifiable:

1. The theory of response developed to date is based almost entirely on slow transient theory in which load conditions and core fluxes are assumed to have reached steady a-c operating condition for each instantaneous value of control current.

2. This theory gives very satisfactory accuracy for time constants down to a few cycles of the supply frequency. Below this only experimental results are available.

3. Both series- and parallel-connected amplifiers without feedback have practically constant time constants over a wide operating range.

4. For the series and parallel connections without feedback, analysis based on a theoretical square saturation curve shows the input and output to be linearly related and the time constant to be actually constant. The main bend of the saturation curve is thus not responsible for the variations of time constant that occur in magnetic amplifiers over their useful range.

5. With high feedback or self-saturation the transfer curve (output versus input) shows more curvature and the time constant measured over the full useful region may be down to 60 per cent of that in the steepest portion of the curve.

6. Nevertheless, even for the self-saturated amplifier, and certainly for the amplifiers without feedback, the time constant appears to be fully as constant over a wide operating range as for many of the machines and other

devices which are so treated in regulating and control-system design.

7. While operation is of principal interest in the approximately linear high gain region, magnetic amplifiers have several modes of operation in various regions. For example, the self-saturating amplifier has four recognizable regions with transition zones between. These are high negative control, unsaturated, high gain region, and saturated. Special consideration will need to be given operation in or through some of these other modes. Operation through the saturated region is important in on-off controls.

It is suggested that response time to 30 per cent, 63 per cent, and 95 per cent of full response after a step input be recognized. The 30-per cent response time would adequately describe the before-saturation delay of an amplifier operated into the unsaturated region. The 63-per cent and 95-per cent response times, which correspond to one and three time constants respectively in a linear circuit, adequately describe response over a prescribed operating region, the lower figure being usable as the time constant in most control calculations.

It is suggested that a time constant be defined and a standard method of test prescribed. The principal points which must be covered in such a definition and suggested requirements are as follows. However, these must be subject to further study, and discussion is invited.

The rated time constant of a magnetic amplifier is the 63-per cent response time after a step input voltage with rated supply voltage, frequency, and load resistance. The step change should cover at least 75 per cent of the useful control range possible without violating the following conditions. The average slope of that part of the transfer curve covered is to be not less than 60 per cent of maximum slope. Operation is to be within the 5-per cent and 95-per cent points of the full range of minimum to maximum output. The power gain under the condition of test is to be stated. The type of circuit and percentage feedback are to be stated.

Discussion

Walter C. Johnson (Princeton University, Princeton, N. J.): The authors have given a very helpful discussion of the present state of knowledge regarding the speed of response of magnetic amplifiers. As they point out, the time constant varies a remarkably small amount over a considerable range, in spite of the fact that a magnetic core of nonlinear characteristics is essential for the operation of the device. In fact, the sharper the bend in the saturation curve, the more constant is the inductance presented to the control circuit. In many ways, a simple saturable reactor behaves much like a nonlinear amplifier with a large amount of inherent negative feedback.

The ratio of amplification to time constant appears to be a potentially useful figure of merit, provided, of course, that it is specified explicitly with regard to the point of operation. A figure of merit is probably most useful when it is dimensionless, and this could be achieved here by expressing the time constant in cycles of the supply frequency.

When a control voltage is applied to a saturable reactor which had been operating previously in an unsaturated condition, there is a finite time delay before an effect is seen in the output current, as the authors point out. An alternate viewpoint in explaining this phenomenon can be obtained from the universal curves of reference 5 of the paper. When plotted on the *E-I* plane, the curves of constant control flux crowd together at small values of load current. Thus, in this region, a small change in both control current and load current correspond to a large change in control flux. This produces a large effective control-winding inductance when the load current is small. The volt-second product supplied by the control voltage is largely taken up at first in increasing the control flux without any great change in load current. This corresponds to the region of large slope near the origin of the magnetization curve shown in Figure 6 of reference 4 of the paper. The universal curves indicate that the curves of control flux are crowded more closely at small values of terminal voltage; therefore, a lowered supply voltage will lead to a greater time delay.

W. J. Dornhoefer, (Vickers Electric Division, St. Louis, Mo.): As the authors indicate in the introduction, the work of standardizing groups on definitions, performance standards, and ratings of magnetic amplifiers has required both theoretical and experimental information concerning response time. The paper contains much of this information, presented in concise and useful form.

This discussion is intended to supplement certain of the information given in the paper, and to offer comments on several of the conclusions and recommendations. The supplementary information, as well as the discussion in general, refers particularly to the self-saturating magnetic amplifier circuit.

The method of calculating the portion of the response time attributable to the control windings (the slow transient) given in the paper is both accurate and useful. In

Figure 1. Comparison of measured and calculated values of K_1 for 35 magnetic amplifiers

Figure 2. Phase shift versus signal frequency

essence, the change in output voltage is used as a measure of the change in average flux linkages in the cores, thus establishing the value of a fictitious control circuit inductance which then may be associated with the control circuit resistance to give the time constant. This method has proved to give an accurate calculated value of the magnetic amplifier time constant for slow transients, as shown in the example given in the paper. As a matter of fact, it seems likely that the calculation gives a more representative value in many cases, because of the errors inherent in measuring the time constant. These errors include the effects of variation of the phase of the step function switching instant and the resolution limits of recording instruments and medium. The latter is of importance because of the need in a time constant measurement for locating accurately the 63 per cent response point on the envelope of the output peaks or average values.

Data, such as that which follows, can be advanced in support of this argument. The data plotted in Figure 1 of the discussion show the ratio of a calculated time constant coefficient to the measured value for a group of 35 self-saturating magnetic amplifiers. The amplifiers have ratings ranging from 0.020 watt to 12,600 watts; supply frequencies from 60 to 800 cycles per second; core materials including 80 per cent nickel-iron alloy, 50 per cent nickel-iron alloy, and grain-oriented silicon steel; circuits including a-c output, single-phase center-tap d-c output, single-phase bridge, 3-phase half-wave, and 3-phase full-wave. The measured value of the time constant was found by applying step-function changes of voltage to the signal circuit and recording oscillographically the growth and decay of the output response to these signals. These measurements were generally made at nominal supply voltage and frequency, and with rated load resistance. The amplitude of the signal voltage step was adjusted to permit amplifier operation in the linear region of the control characteristic, and generally was sufficient to give approximately 10 per cent change of output. Data was taken for a number of values of relative control circuit resistance and the time constant evaluated for 63 per cent response of the envelope of the output peaks. This time constant was then plotted versus resistance on log-log paper, resulting in a 2-part curve. In the region of slow transients, the curve has a slope of -1, while in the region of fast transients, the slope approaches zero. The value of the time constant as the slope approaches zero is the fixed delay due to the a-c windings, while the location of the curve in the region of -1 slope gives the measured value of control winding time constant, as indicated by equation 1.

$$T = K_1 \frac{N_s^2}{R_s} + K_2 \text{ seconds} \qquad (1)$$

where T, N_s, and R_s are used as in the paper, and K_2 is the constant-delay time.

The calculated value of the time constant is found by the formula given in equation 3 of the paper, with the coefficient as given or modified as required for other amplifier circuit connections. For example, for a 3-phase bridge circuit, the relation is

$$T = \frac{\Delta E_L}{\Delta E_s} \frac{N_s}{N_L} \frac{1}{3f} \text{ seconds} \qquad (2)$$

For this circuit, the value of the coefficient K_1 is found from equation 2 as

$$K_1 = \frac{\Delta E_L}{N_s \Delta I_s N_L} \frac{1}{3f} \text{ ohm-seconds} \qquad (3)$$

Figure 1 of this discussion is a comparison of the measured and calculated values of K_1 for the group of 35 magnetic amplifiers. The ratio of the two values is plotted as ordinate on normal probability paper. The median or average value is 99.4 per cent, showing a difference between measurement and calculation of 0.6 per cent over-all. This is not a significant difference for a sample of this size. From this one can conclude that there is no systematic error in either the calculation or measurement method. The fact that the curve shows a normal distribution (straight line on probability paper) indicates that the errors are random and attributable to measurement. It is estimated that the steady-state measurements required to obtain the calculated value of K_1 are accurate to about 2 per cent. (The principal source of error lies in determining ΔE_L, which is an internal electromotive-force change rather than a change in actual load voltage). It also is estimated that the accuracy of measurement of the time constant is limited to between 10 and 20 per cent, due principally to the necessity of approximating the envelope of the oscillograph transient. The deviation of the measured value from the calculated value shown in Figure 1 of this discussion has an rms value (standard deviation) of 13.5 per cent, which is in approximate agreement with the foregoing estimates. It seems likely that the differences between measured and calculated time constants are due to limitations of the accuracy of the measurement. If this is true, the calculation method affords a direct indication of the actual time constant which could be obtained only from a number of direct time-constant measurements.

Limiting Value of Response Time—K_2

The method of calculating the slow-transient time constant given in the paper is not useful when one is interested in fast response, as the authors have pointed out. It is believed that the use of equation 1, to-

Figure 3. Amplifier time constant as a function of relative control circuit resistance

Figure 4. Calculated peak, rms, and average output of magnetic amplifier with ideal output wave form

gether with appropriate values of K_2 will yield sufficiently accurate "fast-transient" results for most practical cases. The range of values which K_2 may have is not known with great accuracy, but it could be determined. The factors, such as rating and geometry, which affect the value of K_2 are known in a general way, and can probably be determined with sufficient accuracy for the purpose, either theoretically or empirically. At present, the possible range of K_2 appears to be slightly wider than the 1/2-to-2-cycle limits suggested in the paper. K_2 values for a group of 44 self-saturating amplifiers of similar diversity to the group of 35 previously described are given in Table I of this discussion.

Table I

	No. of Amplifiers	Values of K_2 in Cycles		
		Minimum	Average	Maximum
A-c output	12	0.5	1.0	2.2
D-c output, 1 phase	17	0.1	0.3	0.8
D-c output, 3 phase, 1/2 wave	8	0.3	0.5	0.9
D-c output, 3 phase, full wave	7	0.5	0.6	0.8
All d-c output	32	0.1	0.4	0.9

Frequency Response Versus Time Constant

The authors have shown that the representation of a self-saturating magnetic amplifier by a single delay is justified by comparison of the measured frequency response of output amplitude with the frequency response calculated from the step-function response and the assumption of a single delay. It is felt that this conclusion is justified, and additional frequency response data based on phase-shift measurements is offered to support it. This phase-shift frequency response data is shown in Figures 2 and 3 of this discussion. Figure 2 shows the measured phase shift of the output envelope of a particular magnetic amplifier plotted versus signal frequency for several values of relative control circuit resistance, and for comparison shows a calculated curve for one value of control circuit resistance. Figure 3 shows two sets of data giving the amplifier time constant as a function of the relative control circuit resistance. One set of data is based on a step-function measurement and the other on phase-shift frequency-response-measurement and the assumption of a single delay in the amplifier.

It is felt that the correspondence found in this phase-shift frequency-response data further justifies the authors' conclusion that the self-saturating magnetic amplifier may be characterized by a single time constant.

Measurement of Response Time

The relation between response time and voltage gain given in equations 3 and 4 of the paper required the use of the change of average output voltage resulting from a change of signal voltage, as the authors have pointed out. For steady-state measurements, the use of simple D'Arsonval instruments makes this a simple matter. When transients are to be studied, the situation is not as straightforward because of the output wave forms which appear. In changing from high output to low output, as shown, for instance, in the oscillogram of Figure 4 of the paper, the output voltage is continuously changing in both form factor and crest factor. In order to construct the envelope of the average output voltage during a transient, it is necessary to integrate the area under each alternation or pulsation of output and plot a smooth curve of the average or integrated output for the duration of the transient. This may then be used in determining the response time. This integration is usually done graphically after the oscillogram of the actual output is made. In special cases, particularly where the transient is relatively slow, the desired result may be obtained directly by the use of an electronic amplifier and an electromechanical recorder with appropriate damping.

It is suggested here that if certain simple precautions are observed, the envelope of the output peaks can be used as a measure of the transient response. This can be done in such a way that the accuracy of the results is not compromised, and at the same time permit a very real saving in the amount of time required and in the cost of making of transient response tests. The data shown in Figure 1 of this discussion are based on peak-value tests and do not appear to include any systematic error, based on the small error apparent in the median value.

Figure 5. Average versus peak output for magnetic amplifier with ideal output wave form

The precaution that must be observed in peak-value transient response testing is simply that the initial value and amplitude of the transient must be restricted so that the change in average value of the amplifier output is approximately proportional to the change in peak value over the required range. Figure 4 of this discussion is intended to illustrate this point. This figure shows the peak, effective, and average outputs of a single-phase magnetic amplifier with ideal output wave form, plotted versus the firing angle. It is apparent from the curves that the above restriction can be satisfied only in the region up to about 40 per cent average output. It is further apparent that the amplitude of the input step and the resulting output change must be small if reasonable proportionality is to be maintained. The fact that the amplitude of the input step must be relatively small for accurate peak-value response testing is further illustrated by Figure 5 of this discussion, which shows the average output of a magnetic amplifier with ideal output waveform plotted versus the peak output. Here it can be seen that the step should be limited to approximately 10 per cent output change. There is no objection to thus limiting the amplitude of the change, because, as the authors have stated, the response time is virtually independent of the magnitude of the signal change.

Conclusions

1. It is felt that the seven conclusions and recommendations set forth at the end of the paper comprise a sound summary of the facts and the present situation confronting the committees of standardization.

2. It is further felt that the authors final recommendation that a standard method of transient response testing be prescribed should be adopted. It is suggested that the recommendation that the step change cover at least 75 per cent of the useful control range should not be adopted without careful consideration of the fact that accuracy of the peak-value response testing method would thus be compromised.

3. The necessity of keeping the method of transient response testing as simple as possible, while assuring that adequate and accurate data are obtained at reasonable cost, is considered to be one of the most important problems to be resolved by the standardizing committees dealing with magnetic amplifiers. The authors of the paper are to be commended on their informative and stimulating contribution to this work.

E. L. Harder and **W. F. Horton:** The authors wish to acknowledge the discussion by Professor Johnson. His explanation of the before-saturation delay phenomenon in terms of universal curves brings out the mechanism of this phenomenon very clearly.

Mr. Dornhoefer has provided a large amount of experimental evidence corroborating the single-delay concept of the self-saturating amplifier. The fact that the calculated time constant affords a direct indication of the actual time constant, which could only be obtained experimentally with a number of measurements, is also well brought out.

In considering the limiting value of response time K_3, the range of values which K_3 may cover in a particular amplifier will depend on the control switching instant and control voltage magnitude in addition to the factors discussed. Since these control circuit conditions may vary widely the specification of a maximum, minimum, and average value of K_3 is probably a useful concept.

Mr. Dornhoefer has clearly brought out the advantages of crest voltage measurement and a small increment (10 per cent) in transient response testing. Some enlargement on the last paragraph of the paper may serve to present the arguments for a larger increment.

The reasons for the three limits given are that if the response is taken over at least 75 per cent of the useful range, the time constant will be a good average of the high and low values that might otherwise be obtained depending on the portion of the range selected. If limited to the 5 to 95 per cent points it will also give the correct time constant for rectangular loop materials having a practically straight line transfer curve between upper and lower limits. If limited to an average slope not less than 60 per cent of maximum, the stated time constant can never be less than 60 per cent of the maximum, and a safeguard is thus provided in using the value in servo analysis.

Now that the arguments have been quite completely stated the committee should be in a good position to make the best compromise. It may be the use of the largest increment over which crest voltage is a fair measure of average voltage.

Transformer Sound Level Considerations

A. J. MASLIN
MEMBER AIEE

Synopsis: The sound level resulting from the operation of a transformer is an exceedingly complex function of the materials, electrical and mechanical design, construction, service and placement of the unit. Some considerations bearing on the origin, transmission, and resulting aural response to such sounds are presented. Means of reducing the sound level and the economic effects of such reduction are mentioned. The presently recognized rules covering test equipment, test methods, and acceptable levels are briefly discussed.

THE sound level of electric apparatus, particularly transformers, has been subject to scrutiny for somewhat more than 20 years. The published information on the subject appears to indicate periods of emphasis roughly corresponding with the turn of each decade. Actually, however, our engineers, research scientists, and magnetic material suppliers have worked on the problem with steadily increasing devotion throughout most of the entire interval. Apparently this year marks another revival of intense interest in the subject by users and manufacturers alike. These intervals of emphasis coincide approximately with periods of major expansion of operating systems, and point up the changing requirements of new practices resulting from growth of load and load density.

During this interval of two decades there have been a number of significant major changes in transformer materials, design, and manufacture, all in the interest of a better, smaller, lighter, and less-costly product. While the problems involving sound level have not been neglected during this period, it is quite evident that there is lack of agreement concerning the suitability of transformers now being manufactured.[1,2] Some British opinion[3] even favors allowing the sound level of transformers to approach that of running machines to permit the use of higher flux densities with correspondingly reduced weights and cost; if not, the new lower loss core materials will only reduce the cost of cooling equipment and not that of the core and coils. This lack of agreement clearly indicates the wide variation of characteristics deemed essential for satisfactory transformer usage by different people in different places. The importance of these desired characteristics, in specific instances, is evident and undisputed.

A re-evaluation of the transformer sound level situation, taking all possible pertinent factors into account, seems to be indicated. To name and describe some of these factors is the purpose of this paper.

Sound Generation

The sound heard as a result of transformer operation is due to force induced vibrations which are ultimately transmitted to the ear of the observer. The most important forces are found in the core where they give rise to core vibration. These core forces depend primarily on the flux density, the characteristics of the core material, and the core construction.

Magnetostriction is a basic property of magnetic core materials and varies among other things with the flux density. It is one fundamental source of the total core vibration, but by no means the whole of it. The two curves of Figure 1 were obtained from the same ring sample of magnetic material. The change in sound level is due solely to a change in the array of the punchings, hence, is not due to a change in the properties of the material. The per-unit amplitude of vibration in the plane of the punchings of a built-up transformer core is frequently identified as magnetostriction.

This may or may not actually be the case. Magnetostriction is important because it determines the minimum possible core vibration for a given core material and flux density.

Other forces which may produce core vibration are associated with joint gaps, nonuniform flux distribution in the core corners, flux interchange to and from the core frames, and so forth. Reduction of these forces and the resulting vibrations is by no means a straight forward process. However, since these forces are among the very few fundamental stimuli subject to control, their mitigation is actively sought through all expedients not inimical to the absolutely required functions of the core.

The effects of load magnitude and power factor on the core forces are manifest chiefly through the change in flux density and flux distribution which they entail. For commonplace operation these effects are fortunately quite small.

When carrying load there are forces between the turns and coils of the same and other windings. There also are forces acting between the core and the coils which depend to a considerable extent upon the symmetry or balance of the coil arrangement. At the present state of the art, for well-designed transformers, these forces do not contribute significantly to the sound level and will merit attention only after the core forces and vibrations have been greatly reduced.

The centrifugal and impact forces attending the operation of cooling fans, pumps, contactors, and so forth, which may be a part of the complete transformer are also causes of vibrations ultimately evidenced as sound. Fans in particular are important sound generators, sometimes producing a level equal to or greater than that of the transformer. Present methods of mitigation involve the use of fans of reduced output or larger than normal transformers with few fans. Depending on the characteristics of the

Paper 50-178, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted February 10, 1950; made available for printing April 26, 1950.

A. J. MASLIN is with Westinghouse Electric Corporation, Sharon, Pa.

transformer there may be as much, or more, room for improvement in cooling fans as there is in the transformer itself.

The vibrations set up by the forces described, particularly those of the core, may be large or small depending upon the mechanical characteristics of the structures on which they act. To limit the amplitude of these vibrations it is evident that the natural periods of the structures must not be the same as the periods of the driving forces. The natural period of some parts of the transformer structure can be predetermined with reasonable accuracy[4] but other parts defy such treatment.

The vibrations so generated are transmitted to the surrounding air by way of the liquid which occupies the space between core and tank, and by means of the mechanical ties between core frames and tank. Transmission is generally achieved with some attenuation. The resulting tank vibrations drive the air. Mechanical resonance must be avoided throughout this transmission path, which, as has been indicated, is in part an empirical procedure.

Sound Level and Aural Response

The relationship between sound level (decibels), intensity level (decibels), loudness level (phons) and loudness (loudness units or sones) for plane wave pure tones of known frequency is relatively direct.[5] Sound level meter reading (A, B, or C weighting) may be converted to intensity level by means of the appropriate response-frequency characteristic.[6] Intensity level is converted to loudness level using the well known equal-loudness contours,[7] and loudness level to loudness through a curve[8] or formula[9] relating these quantities.

For complex sounds, however, the procedure is more complicated and involves the consideration of harmonic components either separately[10] or by bands.[11] The indication of the sound level meter for complex sounds practically defies description in terms of acoustic quantities.[12] It does, however, fulfill a need. Objections to the meter and its use should be supported by constructive recommendations covering the quantity that should be measured in order to minimize such objections. Also due consideration for the equipment and test procedure required to measure this quantity must be given.

Sound Level Reduction

The fundamental approach to sound level reduction is of course by reduction of

Figure 1. Sound level of a sample of magnetic material for two different arrays of the punchings

the responsible driving forces. Research and material engineers have made every effort to reduce the magnetostriction of the newer magnetic materials with considerable success. Magnetostriction of the core material is at present beyond the control of the transformer design engineer. Every known means consistent with the absolutely essential functions of the various parts of the transformer structure are being employed to reduce the other driving forces. When these other forces are reduced to the minimum attainable magnitudes, and the resulting vibrations likewise held to minimum amplitudes, the flux density is virtually the only variable under the immediate control of the designer.

Reducing the sound level below the recommended standard level[13] by reducing the flux density is more effective and less costly for large transformers than for smaller ones. The curve, Figure 2, indicates approximately the increase in equivalent kilovolt-amperes resulting from reductions of 3, 6, and 9 decibels below the National Electrical Manufacturers Association (NEMA) recommended levels for oil- and air-cooled transformers, when the reduction is effected by lowering the induction in the core.

It is well known that a change of 10 per cent in induction will result in a 2- to 3-decibel change in sound level. Thus, for a 6-decibel reduction, the core weight may be expected to increase about 30 per cent. The larger core, for the same number of turns and the same copper loss, will require about 30 per cent more copper. This increase in weight of active material from 100 to 130 is approximately equivalent to a transformer having a kilovolt-ampere rating of 142 per cent based on the flux density of the original unit which met the NEMA recommended sound level. However, as will be indicated later, the NEMA recommendations permit higher inductions in larger transformers than in smaller ones. This fact, together with other design considerations, causes the equivalent kilovolt-amperes of small transformers to exceed and of large transformer to be less than, the above figure of 142 per cent for 6 decibels. Thus the curve, Figure 2, shows 250 per cent for a 2,500-kva unit having a NEMA level of 65 decibels and 130 per cent for a 25,000-kva unit having a NEMA level of 75 decibels, for the same 6-decibel reduction.

Reduction of the coil driving forces is, in general, limited to providing coil arrangements of maximum symmetry.

Reduction of the vibration of the driven members can be achieved by increasing their mechanical impedance and eliminating resonance. Other factors in the design of the transformer restrict the mechanical impedance of the structure to a relatively narrow range so that the avoidance of resonance is the important means of control. This is done, where possible, by calculation in advance of construction. However, the complexity of the mechanical system defies analysis in many parts, hence, empirical and experimental corrections are frequently required.

Sound level reduction by increasing the attenuation of the mechanical or acoustical circuit between the source and the observer has been repeatedly advocated. The use of isolating or attenuating barriers or suspensions between the core and the tank would be more attractive if they could be effectively and economically applied. If sound attenuation were the only problem to be considered, this solution would doubtless have been long since employed. However, electrical, thermal, physical, and economic factors as well as longevity considerations have discouraged manufacturers from promoting this possibility.

The use of vibration absorbers between the transformer and its supporting foundation is effective only when the foundation transmits vibrations to another sound radiator. Such absorbers are frequently the cure for an intolerable condition when the transformer is located in a building vault, mounted in an overhead structure, or when the foundation communicates directly with bedrock.

Barriers external to the transformer also have been advocated and used.[2,14,15] This solution has taken the form of complete enclosures, roofless enclosures, and partially surrounding walls. To be effective the enclosure must have a low transmission coefficient which usually requires appreciable mass per-unit surface

area. The effectiveness of enclosures is enhanced by lining with a material of high absorption coefficient. Roofless or partial enclosures are less effective particularly at a considerable distance from the source, due to diffraction at their edges. Accurate predetermination of the effectiveness of an enclosure, especially a partial one, does not appear feasible, although there is some information available.[14,15,16,17]

External barriers, in addition to alleviating the sound nuisance of transformer substations, permit camouflage of the installation into esthetic harmony with its surroundings. This factor should be considered when deciding whether the added cost of a quiet installation should reside in the equipment itself, or in an enclosure.

The physical size of transformers has some influence on the sound level at an appreciable distance. If two transformers of different sizes have the same sound level at one foot, the smaller unit will have a lower level than the other at a distance fairly large with respect to its dimensions.[18]

Sound Level Standards

The presently recommended sound levels have been criticized as being too high, as being nonindicative of observer reaction, and as being poorly related to transformer rating. These objections are probably all perfectly valid from particular viewpoints. It must be recognized, however, that wide variations of viewpoint are inherent and justified.

Not all the transformers manufactured are installed where sound level is an important consideration, even though the proportion of such units is increasing. The rating of units installed in residential or business districts is also increasing very rapidly. Not long ago 2,000 kva was considered fairly large, but today units of 20,000 or 30,000 kva or more are located in close proximity to residences and business buildings. Furthermore, there appears to be a tendency to specify substandard levels, whether presently needed or not, as a hedge against possible population growth or relocation of the unit.

To build transformers with lower than standard inherent sound levels is inescapably more costly at the present state of the art than to build units to standard levels. Any "standard" that would require the purchaser to buy a Cadillac when he would be well served by a Chevrolet is unrealistic. Conversely, for example, it is probable that present levels for dry-type transformers are similarly high for certain applications of that equipment. It seems necessary, therefore, to revise the recommended levels to better suit the various requirements. However, before this can be done agreement must be reached as to what these requirements really are and how they shall be specified and measured.

Present test methods and test equipment admittedly do not give a close measure of listener reaction. They do permit the easy determination of relative values. To arbitrarily change from the A to the B or C weighting scale, or to take readings at 5, 10, or 50 feet instead of one foot will not sensibly improve this condition. If the present equipment and procedures are untenable, profound study is required to determine satisfactory objectives and practical means of obtaining them.

Based on certain assumptions it has been shown[19] that the sound level of a transformer may be expressed

$$DB = K_4 + 6.67 \log W$$

where W is the weight of the core and K_4 is a constant determined by design proportions, induction and reference level. Since the relationship between core weight and kilovolt-ampere rating is

$$W = k(KVA)^n$$

substitution affords

$$DB = K + 6.67n \log (KVA)$$

where $K = K_4 + 6.67 \log k$. This relation, for $K = 56$, $n = 0.75$, together with NEMA recommended levels for oil- and air-cooled transformers 69 kv and below, is plotted in Figure 3. The two curves meet at 1 kva and at 100,000 kva. Obviously the NEMA levels for intermediate ratings are lower than the normal relationship. This is one of the reasons why it is relatively so much more costly to reduce the sound level of a small transformer than a large one, as illustrated in Figure 2.

Conclusions

In spite of diligent research on materials, their treatment and use, test analysis, design and model work, all of which has enabled the engineer to design to a specific sound level, with assurance that test results will agree with calculated values with good engineering accuracy, it is still an expensive procedure to produce transformers with substandard sound levels. Since the recommended standard sound levels are not naturally related to transformer rating, the increase in cost for a given reduction below standard levels is greatest for the small and medium sizes of power transformers.

The use of enclosures to afford low sound level is effective and frequently employed, but also is costly. The choice between inherently low level equipment and "standard" equipment with an enclosure, should be based on economic and esthetic considerations.

In view of the steadily increasing requirement for low sound levels it may be desirable to establish at least two sets of standard levels. One set defining levels attending normal equipment which fully utilizes modern materials and technics while meeting the specified electrical, thermal, and other characteristics, another set specifying levels considered acceptable for all considerations, for locations where audible sound is a critical factor.

Figure 2. Equivalent kilovolt-amperes required to effect reductions of 3, 6, and 9 decibels below recommended levels by decreasing core induction

Figure 3. Theoretical variation of sound level with kilovolt-amperes compared with NEMA recommended level

While sound level meters and standard test procedures do not yield an accurate index of aural response under field conditions, and are subject to varied interpretation, a change from present equipment and practice should not be lightly undertaken lest new undesirables be traded for old.

Discussion

T. D. Gordy (General Electric Company, Pittsfield, Mass.): The study of transformer sound levels is a very complex problem, as is shown by Mr. Maslin's paper. Not only is each component of the problem complex, but the way in which the various components are related in an acousto-mechanical-electrical circuit is complicated.[1] The paper discusses major sound generation sources, and comments on the importance of magnetostriction are in order. Sources other than magnetostriction exist, but as is stated in the paper, minimum possible core vibration for a given core material and flux density is determined by magnetostriction.

Mr. Maslin's comments on test methods and test equipment are most timely. These methods and equipment are not perfect for measuring aural effects on the listeners, but they do serve as a tool and guide by which the transformer designer can evaluate his designs. Regardless of the weighting scale used or distance from the transformer to the microphone, methods and equipment do exist that give the designer relative values of sound level. Admitting the weakness of our present transformer noise standards,[2] it is questionable whether present Standards should be changed until more study is given to the various weighting scales and sound meters.

Derivation of the equation

$$DB = 56 + 5 \log (KVA) \quad (1)$$

of Figure 3 and its relation to curves of Figure 2 are somewhat confusing.

The equations

$$DB = K_4 + 6.67 \log W \quad (2)$$

$$W = k(KVA)^n \quad (3)$$

should apply to a certain kilovolt-ampere range of transformers, but it is doubtful if they apply to transformers from 1 to 100,000 kva. Combining equations 2 and 3, there results the equation

$$DB = C_1 + C_2 \log (KVA) \quad (4)$$

in which C_1 and C_2 are constants. Generally speaking, transformers from 1 to 300 kva or 1 to 500 kva are built differently from those larger than 300 or 500 kva. Stepped changes in NEMA sound level limits become effective at 300 kva, because below that value, a level of 56 decibels is permitted for any kilovolt-ampere value. Only between 300 kva and 100,000 kva do NEMA sound levels vary with the kilovolt-amperes. Hence, to evaluate C_1 and C_2 of equation 4, select these two end points of the NEMA limits. Imposing oil-to-air cooled transformers (69 kv and below), boundary conditions of 300 kva, 56 decibels and 100,000 kva, 81 decibels on equation 4, solving simultaneously for C_1 and C_2, then substituting values of these constants back into equation 4, there is obtained

$$DB = 31.5 + 9.9 \log (KVA) \quad (5)$$

This equation plots as shown in Figure 1 of this discussion.

It is seen that this normal relationship of equation 5 agrees very closely with the NEMA levels. Even if equation 5 be extrapolated to smaller kilovolt-amperes, where it justly should not be used, results are reasonably close to actual sound levels obtained. For a 1-kva transformer, the sound level of 31.5 decibels is obtained. This is much closer to the noise level of 1-kva transformers than is 56 decibels as given by equation 1. The conclusion may be drawn that equation 1 is not necessarily a normal relationship between decibels and kilovolt-amperes; but when appropriate constants are obtained for this form of equation, a relation is obtained that not only follows the general equations 2 and 3 but gives results that are close to tested transformer sound levels, and agree with the NEMA levels.

Figure 1. Modified theoretical variation of sound level with kilovolt-amperes compared with NEMA recommended level

Curves of Figure 2 of the paper show a very large variation of per cent equivalent kilovolt-amperes with NEMA sound level for 3-, 6-, and 9-decibel reductions. This is difficult to understand when the ordinate of the curves is expressed in per cent kilovolt-amperes. Assume that a 3-decibel reduction in sound level is desired. Let the core cross-sectional area and copper cross-sectional area be held constant. To obtain a 3-decibel reduction, flux density would have to be reduced 10 per cent. To obtain the original rated voltage, winding turns would have to be increased 10 per cent. Each of these extra turns would have the same copper cross-sectional area as each of the original 100 per cent turns. Hence, the winding kilovolt-amperes in terms of the original 100 per cent kilovolt-amperes becomes 110 per cent. To accommodate these extra 10 per cent turns, a slightly larger core window would be required, but this would change the decibel level by a small amount. In an actual design, both turns and core cross-sectional area would be changed so that the net result would be about 10 per cent increase in equivalent kilovolt-amperes for a 3-decibel reduction.

In the foregoing discussion, kilovolt-ampere rating was not introduced. Hence, the equivalent kilovolt-amperes expressed as a per cent is not a function of the kilovolt-ampere rating of the transformer. Therefore, curves of Figure 2 in the paper should be essentially horizontal. More than likely when covering the NEMA sound level range from 60 to 85 decibels, a change in winding voltage would be encountered; and necessarily, some changes in the basic type of design would be made. These changes probably would tend to make the per cent equivalent kilovolt-ampere versus NEMA sound level curves not horizontal and would give them a slight curvature of the type shown in Figure 2. It is difficult to understand how the per cent equivalent kilovolt-amperes given by Figure 2 can be obtained when a change of from 2 to 3 decibels for 10 per cent change in voltage is the starting point for determination of the curves.

Mr. Maslin has covered the important points of transformer sound level considerations as viewed by the manufacturer. Some of these viewpoints conflict with users' viewpoints as would be expected. Close cooperation between manufacturers and users of transformers appears to be a most logical way to bring the conflicting viewpoints into compromise.

C. S. Murray (Consolidated Edison Company of New York, Inc., New York, N. Y.): The author states that engineers, research scientists, and others have worked on the problem of apparatus sound level for over 20 years. This is not to be questioned, but let us look at what has been accomplished in the field of transformer noise.

Sound level measurements were made on a number of the larger 3-phase transformers installed on our system which have been in service for from 15 to 20 years. These transformers range in kilovolt-ampere ratings from 22,500 to 70,000 and in voltage from 27 to 132 kv. They were purchased without any regard to noise level. In all cases the tests were made with the transformers in service and carrying load and in many instances these transformers are in close proximity to large reflecting surfaces. And yet, in a majority of the tests, the average sound level was from 8 to 10 decibels below the values now specified by NEMA Standards. It is questionable whether transformers purchased today under similar conditions will be as quiet.

There is no doubt that there has been great improvements in transformer materials and design over the last few years. There is some doubt, however, as to whether the problem of noise was given just consideration. When better core material was made available, the core was made smaller and worked at higher flux densities. This resulted in a smaller physical size and reduced weight of transformer but in many cases the noise level was increased.

The author, by means of Figure 2 of his paper, would have you believe that material reduction of transformer sound level below that specified by NEMA can be obtained only by lowering the induction in the core which would result in increased equivalent transformer rating. Using these curves and extrapolating where necessary, it will be found that decreasing the sound level of 500- and 1,000-kva 3-phase transformers by 9 decibels would mean an equivalent increased transformer rating of approximately 1,000 per cent. Yet there are installed on our system a number of 500- and 1,000-kva distribution transformers that have sound levels 10 decibels below the specified NEMA level and they have no more iron, no better iron, or are they larger than similar transformers having NEMA specified values. The lower ratings of transformers are considered here since the author shows in his paper that it is relatively so much more costly to reduce the sound level of a small transformer than a large one.

Others[1,2] have given their experiences for transformers of higher rating and the results are similar.

These results indicate that it is possible to build transformers with a sound level considerably below that specified by the NEMA without resorting to the "brute force" method of lowering the induction in the core and without appreciable cost to either the manufacturer or the user.

The author discusses the sound level meter and states that it has fulfilled a need. It is a fact that without the sound level meter many of the acoustical problems that have arisen in the operation of electric equipment would have gone unsolved. However, those of us who have made considerable use of the meter over a period of years believe that the time has come for something better. It has been the practice in our organization for some time to use a sound analyzer in connection with the sound level meter when making noise tests on any apparatus on the system. Considerable data have been obtained which show that a particular component of the noise emitted by the apparatus is usually the cause for a noise complaint at a remote distance. And yet that component may be such that its presence does not change the indication of the sound level meter. There are a number of cases wherein the hum from a transformer could be easily heard several hundred feet from it and was considered objectionable. The indication of the sound level meter, however, remained the same when the transformer was de-energized.

For each and every one of us to set down our requirements for a meter would probably result in as many different sets of requirements as the number of persons submitting them. It is up to some standardizing body such as the American Standards Association to recognize and arrive at a solution to the problem. It is felt that the standardization of a sound analyzer with proper filter circuits is of great importance at this time. Once the sound analyzer is standardized and greater use made of it by the power engineer, the requirements for a noise meter may be better defined.

2. See reference 14 of the paper.

A. J. Maslin: Mr. Gordy's discussion is most welcome because it emphasizes some of the more important points made in the paper. Concerning some others there is evident misunderstanding.

Mr. Gordy has obtained his equation 4 from equations 2 and 3 of the discussion. Thus, the constants C_1 and C_2 are, in turns of $K_4 k$ and n

$$C_1 = K_4 + 0.67 \log k$$

$$C_2 = 6.67n$$

In going to equation 5 therefore Mr. Gordy says

$$n = 1.485$$

From equation 3, however, n is the exponent which applied to the kilovolt-ampere rating gives proportionality with core weight. As is well known to all transformer designers, $n = 0.75$ for any geometrically similar line of transformers. This is readily demonstrated theoretically and is borne out in practice. When the range of kilovolt-ampere rating is large enough that geometrical similarity no longer exists the value of n is less than 0.75. Mr. Gordy's value $C_2 = 9.9$, which was chosen arbitrarily to make the slope of his curve match that of the NEMA levels, therefore cannot be justified. If Mr. Gordy prefers to locate his curve so that it passes through 56 decibels at 300 kva it must then pass through 68.6 decibels at 100,000 kva. The important point, however, as brought out in the paper, is that the relationship between kilovolt-amperes and sound level as prescribed by NEMA is not a natural one. In practice this means that the core induction for medium-sized transformers must be lower than the induction for very large, or very small, units if NEMA levels are to be met.

In discussing Figure 2 of the paper Mr. Gordy presents some interesting figures. By holding the core cross section and the copper cross section constant, reducing the induction by 10 per cent, and increasing the number of turns by 10 per cent, he has built a transformer having 100 per cent of the rating, 110 per cent of the load loss and a 3-decibel lower sound level than the reference unit. This transformer does indeed have an equivalent rating of about 110 per cent; that is, at the induction of the reference unit the transformer described by Mr. Gordy will have 110 per cent of the reference rating. What the customer wants, however, is the same rating, 3-decibels lower sound level and the same load loss referred to the reference unit. To achieve this it is necessary to increase the copper cross section by at least 10 per cent. Thus, on the basis of the example Mr. Gordy has chosen, the winding capacity is increased more than 20 per cent. Obviously it is impossible to put 110 per cent turns of 110 per cent cross section in the original core window, so the equivalent ratings of the core and winding are still further increased. In practice, of course, core cross section, number of turns, and copper cross section would all be changed, but the increase in equivalent kilovolt-ampere ratings is not reduced thereby. The curves, Figure 2 of the paper, were actually obtained from a large number of designs covering a wide range of kilovolt-ampere ratings and voltage classes. Quite obviously one curve cannot apply to all voltage classes, hence, as stated in the paper, Figure 2 indicates approximately the increase in equivalent kilovolt-amperes resulting from the stated decibel reductions.

Mr. Murray's discussion is valuable since it reflects the thinking of a user of transformers. He takes the manufacturer to task for building noisier equipment today than he did 15 years ago. It is, of course, true that improved materials and design have permitted higher flux densities. These higher flux densities have been used in ordinary circumstances up to a limiting value imposed by sound level standards. It is Mr. Murray's contention that this should not have been done. However, there is another factor to be considered. During the past ten years labor and material costs to the manufacturer have increased from 80 to 90 per cent. The cost of transformers to the user, on the other hand, has only increased about two-thirds that amount. This state of affairs has been made possible by using the improved materials and design mentioned by Mr. Murray, and by hewing closer to the standard sound levels. If the cost of transformers to the user had been allowed to match the increase in labor and material costs, present-day transformers would be at least as quiet as the older units Mr. Murray mentions. With these factors in mind it is questionable whether all users will agree with Mr. Murray.

The discussion of Figure 2 of the paper has been covered before. However, it should be emphasized that extrapolation of the curves is not permissible because for small units the equivalent rating decreases again. The equivalent kilovolt-ampere rating is a function of the ordinate between the two curves of Figure 3 of the paper. Quite obviously there is something seriously amiss in the noisier 500- and 1,000-kva units mentioned by Mr. Murray if the quiet and the noisy units compare as stated.

Mr. Murray's comments concerning sound level meters point toward an ideal which would be most welcome. The design, construction, and use of such a "calibrated ear" meter must present unusual difficulties, otherwise we could reasonably expect that one would have been developed. Such an instrument should, for example, eliminate the need for telephone interference factors as well as satisfy the requirements of the power engineer. It is hoped that a more satisfactory meter will be made available and that satisfactory performance of transformers sound-wise will be forthcoming through the co-operative effort of all concerned.

Quiet Transformer Installations—A Problem for Both Equipment and Substation Designers

I. S. MENDENHALL
MEMBER AIEE

F. L. TAYLOR
NONMEMBER AIEE

Synopsis: The problem of achieving quiet installations of transformers at substations is one that requires the efforts of both the equipment designer and the substation designer for successful solution.

This paper describes remedial and preventive measures that have been taken by The Detroit Edison Company to solve the noise problem in substations. The most effective method that was tried was to enclose the transformers on four sides with a 12-inch masonry wall, this effecting a sound reduction of about 24 decibels. Other measures, which were less effective acoustically, also are described and data given.

THE problem of the reduction of the noise emanating from substations is one that is being faced by many electrical utilities, and it is one that is likely to become more acute in the future. The problem arises from several causes, among them being the necessity for locating substations in or adjacent to residential areas; an increase in the size of transformers and regulators, due to increasing load densities; and a seeming trend on the part of some manufacturers toward producing transformers having higher noise levels than previously. Figures 1, 2, 3, and 4 are aerial photographs showing the locations of four substations of The Detroit Edison Company with respect to residential and commercial areas.

It is recognized that it may never be economically feasible to build the larger transformers so quiet that they could safely be installed in residential areas without provision for reducing the sound level. The problem, therefore, must be attacked both by the equipment manufacturer, particularly of transformers, and by the substation designer.

This paper discusses measures that have been taken by The Detroit Edison Company to confine the sound that originates in outdoor transformers and regulators, and does not consider the problem of the abatement of noise from other sources, such as air-blast equipment or rotating machinery. Similar measures with some modifications would be of value, however, in other applications.

The first and most obvious approach to the problem of the reduction of noise from substations is to attempt to get quieter transformers and regulators from the manufacturers. This suggestion has been made in other papers[1] and its importance should be stressed again. Experience has shown that it is possible to build a transformer having a noise level many decibels below the value specified in the National Electrical Manufacturer's Association (NEMA) standards, without appreciable increase in cost. For example, The Detroit Edison Company, in the period of 1938 to 1940, received transformers of 1,500-, 2,500-, 4,000-, and 6,000-kva capacity, having sound levels respectively of 56, 57, 60, and 62 decibels. The corresponding sound levels permitted by the NEMA standards are 63, 65, 66, and 68 decibels. It is obvious that there is an opportunity, as well as a need, for the manufacturers to acquire sufficient experience and data so that they can consistently build transformers having sound levels as low as the best units that are built occasionally.

Paper 50-179, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted November 15, 1949; made available for printing April 26, 1950.

I. S. MENDENHALL and F. L. TAYLOR are both with The Detroit Edison Company, Detroit, Mich.

Shrubbery

A method that has proved satisfactory, under some conditions, is the planting of evergreens and shrubbery around a substation. In one instance, an outdoor substation was built facing a main highway, in a high-income suburban residential area. Readings of noise showed that the sound level at the highway, due to the substation equipment was about 43 decibels, whereas the intermittent sound level at that point, due to traffic was about 75 decibels. The nearest house was on the opposite side of the highway from the substation and about 200 feet distance from the latter, but nevertheless there were complaints about the noise from the substation.

A heavy planting of evergreens, shrubbery, and trees was made around three sides of the substation fence, see Figures 5 and 6. This reduced the noise sufficiently so that the complaining customer was satisfied, and in addition the appearance of the installation from the highway was greatly improved. Unfortunately, from the standpoint of obtaining data, the transformers were changed out for load reasons shortly thereafter so that no noise readings were obtained that would indicate the actual effectiveness of the shrubbery in reducing noise. This method is worth considering, however, where the noise problem is not severe.

Masonry Walls

The next method that was tried was to surround the transformer and the bus regulator with a masonry enclosure. This was done by using the rear wall of the substation building as one side of the enclosure and completing it with three walls of cinder block, with a brick veneer on the outside to match the building. The walls are 12 inches thick and high enough to extend about five feet above the top of the transformer tank. The enclosures

Figure 1. Aerial view of Turner Substation and environs

Figure 3. Aerial view of Cortland Substation and surrounding area

Figure 2. Aerial view of Balfour Substation and vicinity

Figure 4 (above). Aerial view of Puritan Substation and vicinity

Figure 5 (below). Rear view of Franklin Substation

are open at the top, although in some cases they are covered with screening to prevent the entrance of birds. The space between the transformer or regulator and the walls is three to six feet. No difficulties have been experienced with overheating of the equipment.

There is a service door for access to each enclosure, but the removal of a transformer or regulator necessitates tearing down a part of the wall. To facilitate this operation, "through-joints" are provided in the wall at two places so

Figure 6 (left). Franklin Substation as seen from the highway

Figure 8 (right). Elevation of Coolidge Substation, with sound readings

that a panel may be removed independently of the remainder of the wall.

Figure 7 shows the transformer enclosures at a substation having this type of construction. Figures 8, 9, and 10 show the sound readings at this location.

A variation of this type of installation that is used where noise reduction is less of a consideration, but nevertheless some noise insulation as well as protection is needed, consists of a masonry enclosure as above, having a removable sheet-metal panel for the removal of equipment. A typical design utilizes 20 gauge sheet-steel roof decking which has ribs formed in the material for stiffness. Removable panel area is divided into independent sections weighing a maximum of 125 to 150 pounds each for facility in erection and removal. The panel sections are bolted to suitable steel members which, in turn, are removable, thus leaving a clear opening of adequate size to move the equipment in or out.

The removable steel panels have an advantage over the masonry panels in initial cost, removal and replacement cost, and in the time required to remove and replace them. The steel panels, however, are somewhat less effective than masonry in reducing sound transmission.

An installation of removable steel panels is shown in Figures 11 and 12.

Sound readings taken at a substation of this type are given in Table I. See also the diagram in Figure 13.

In an effort to improve the sound insulating characteristics of the removable panels, while retaining their advantages, an installation of panels filled with glass fibers was made. These panels have glass fiber batts two inches thick, completely enclosed in 20 gauge sheet steel.

Table I

	Decibels
Transformer sound level, measured in the open	66
Average sound level inside the enclosure, adjacent to the steel panels	69
Average sound level outside the enclosure, 3 feet from the steel panels	67
Average sound level outside the enclosure, 12 feet from the steel panels	52
Sound reduction through panel	12

Table II

	Decibels
Transformer sound level, measured in the open	69
Average sound level inside the enclosure, adjacent to the removable panel	67
Average sound level outside the enclosure, 5 feet from the panel	48
Sound reduction through panel	19

They were made in sizes such that they can readily be handled during erection, the maximum weight being about 150 pounds. They are held in place by through-bolts attaching them to removable steel members which extend across the opening in the wall. Figure 14 shows an installation of this type.

This material proved to be considerably better than sheet steel as a sound insulator, as was expected, and was almost as effective as a masonry wall. Sound level readings taken at this installation are shown in Table II.

Figure 15 is a diagrammatic plan of an installation of this kind, showing the complete set of sound readings that were taken.

Comparison of Panel Types

The practical value of any new development must always be determined on the basis of the benefits as compared with the costs. Each of the three types of closure for transformer enclosures has certain advantages and other disadvantages.

The removable steel panels have the minimum initial cost and may be quickly and cheaply removed and replaced, but their noise insulation capabilities are inadequate, for many locations.

The removable section of brick wall has the second lowest initial cost and the best sound absorption of the three types. The initial cost plus the cost of one removal and replacement, however, is as great as that of the most expensive type of panel (glass fibers), and after two or more removals and replacements the total cost becomes the highest of all.

The removable glass fiber panels have the highest initial cost, but this becomes equal to the cumulative cost of the brick panels after one removal, and becomes less after two or more removals. The sound absorption is only slightly less than is provided by brick. For most substations in residential areas, where good noise insulation is a necessity and provision must be made for changing the transformers to larger sizes, the glass fiber panels appear to be the best compromise that has been developed so far.

Table III gives a comparison of the sound insulating qualities and of the relative costs of the three types of panels, as determined from the experience of The Detroit Edison Company. The costs are for the panels only, installed in place, and do not include the cost of the masonry walls for the remainder of the enclosure.

The curves shown on Figure 18 summarize the results of tests of sound attenuation through panels of the three types, with various sound levels inside the enclosures.

Case History of One Substation

At the substation shown in Figure 1, the three transformers were originally installed in an open yard. Each unit was of 6,000-kva capacity. Although the location was such that there were residences within about 50 feet of the transformers, no noise complaints were received from the neighbors due to the fact that the quietest available units had been selected for this substation. These transformers had an average sound level of 60 decibels.

It became necessary to change the transformers to 10,000-kva units because of load growth, and immediately thereafter the nearest neighbor complained that the noise from the transformers disturbed him. A check of the sound level in the area showed that the complaint was justified. Masonry walls, 20 feet high, were built around three sides of the transformers, the open side of the enclosures being toward the substation building and away from the houses. Following this, sound level readings, and interviews with the complaining customer and others in the area, disclosed that the sound level was very satisfactory.

Figure 16 shows this substation, with a partial view of the masonry cells that were added. Figure 17 is a diagram and plan view of the substation, which shows the readings of sound level that were taken before and after the construction of the masonry cells.

Method of Sound Measurement

In this discussion it is assumed that those interested in the subject of noise abatement are familiar with noise meters and their use. The meter used on these tests was of standard design, and provided with an air blown whistle for overall calibration. 40-decibel weighting was used on all tests, regardless of the sound levels encountered. Measurements were made on the ground, and also in the air above one station, see Figure 8, but like locations were not measured at each station. Conditions also varied from station to station. In some cases, noise was measured before and after installing panels, while at other locations the noise was measured only after completing the enclosure. More data would have been desirable but weather conditions and lack of time interfered.

The curve given in Figure 18 was drawn from data obtained in the field, after it was noticed that similar walls did not always provide the same decibel attenuation. The origin of the curves is at zero decibels and from these curves it would appear that the attenuation for a given wall varies with the intensity of the transformer noise level. The attenuation shown is less than given in data published previously.[3] This condition is probably due to leakage over the top of

the wall. Further investigation to supplement the data contained in the curves would be desirable.

Conclusions

The problem of minimizing the noise that is emitted from substations is becoming increasingly acute to electrical utilities. A satisfactory solution that has been evolved by this company consists of enclosing the outdoor transformers and regulators with masonry walls. Removable panels are provided in the walls to allow removal of the equipment.

Three types of material have been used for the removable panels: masonry block, ribbed sheet steel, and glass fiber batts enclosed in sheet steel. The order of effectiveness of the three types in reducing sound transmission is: 1. masonry block; 2. glass fibers; 3. ribbed steel.

Discussion

R. R. Peck (Southern California Edison Company, Los Angeles, Calif.): This paper is of particular interest to utilities now seeking a solution to the noise problem. The study shows that the use of masonry walls for sound barriers is an effective method of quieting transformer noise. The use of the removable metal-fiber glass panels is important, since it makes the exchange of transformers possible without destroying the barrier. This has been one of the major drawbacks in the use of heavy masonry construction.

Barriers, however, should not be considered as the ultimate solution to all noise problems because of their many disadvantages:

1. A barrier, to be effective, must "fit" the noisy transformer. A new transformer of larger size or of different dimensions may require a different barrier. A change in a masonry barrier is expensive and time-consuming.

2. The optimum distance between the noise radiating surface and the barrier is about four feet. In some cases, considerably more operating space is required and at times the transformer cooling may be impaired by the proximity of the barrier.

3. An efficient sound barrier is not necessarily a thing of beauty, and unless considerable work and money are spent to improve the appearance, it may be unsightly and overcome the advantages gained by the lower noise level.

4. The cost of the barrier adds to the cost of the substation and, hence, changes the economics of the over-all distribution system. In isolated cases, this may not appear to be a problem, but as the number of applications grows it becomes a major consideration.

The manufacturers have offered a transformer with a noise level of 10 decibels less than the National Electrical Manufacturers Association (NEMA) standard for an additional charge of 25 per cent on the transformer price. This 10-decibel reduction below NEMA standards is rarely adequate in itself, and usually requires a further expenditure to make it acceptable.

It is our opinion that the NEMA standard for outdoor transformers to be installed in residential areas is too high and should not have a stair-step rating. If a noise is objectionable it makes little difference whether the noise comes from a 2,000- or 3,000-kva transformer, whether it is rated 69 kv or 132 kv. Ultimately transformers used in this class of service should have a flat decibel rating.

The problem now returns to the design engineer with the request for much quieter transformers at a cost that will make their use feasible from an economical standpoint.

T. D. Gordy (General Electric Company Pittsfield, Mass.): Mr. Mendenhall and Mr. Taylor have contributed data on transformer enclosures which is important to system engineers placing transformers in commercial and residential areas. Even though lower-than-present noise level transformers are desired from manufacturers, the paper demonstrates that present transformer installation levels can be lowered by properly designed enclosures. Whether this is the most economical method of obtaining the necessary noise levels of installations, or whether lower noise level transformers should be installed without walls, remains to be determined.

Figure 18 of the paper shows panel attenuation to be a linear function of the decibels of the noise source. Probably these curves were drawn from data obtained on several different installations. Spacing of the panels from the source and frequency composition of the noise source could cause a variation of attenuation with source decibel. Particularly, the effectiveness of the steel and fiber glass panel would be dependent upon frequency composition of the noise source. Also, high source decibel may be associated with high walls; leakage over the wall as detected in the proximity of the wall would vary, particularly if the various sources have different frequency compositions. The paper points out the possibility of leakage over the top of the wall affecting

attenuation, and the effect of frequency could be included in further investigations.

A. J. Maslin (Westinghouse Electric Corporation, Sharon, Pa.): The authors have presented a wealth of valuable data and constructive comment on the subject of sound nuisance alleviation.

The trend, mentioned in the paper, toward higher sound levels on the part of some transformer manufacturers appears to me to be quite natural. For transformers built with the older or poorer grades of hot rolled silicon iron, the normal flux density was determined by the no-load loss or excitation guarantees at a relatively low value. The sound level, though low, was incidental. With the introduction of newer, better iron alloys, particularly oriented silicon iron, the flux density for a given loss or exciting current could be increased materially. While for a given induction the new materials are generally better sound-wise than the old, the increase in flux density permitted by lower loss and higher permeability more than offsets this. As a result, new transformers tend to be smaller, lighter, and louder than their precedents. However, a point that is frequently overlooked is that the user has profited by this change.

During the past ten years the cost of labor and materials has increased about 85 per cent. The increase in price of finished transformers, on the other hand, is from 25 to 50 points below this figure, and the transformers are better in all respects except possibly sound level. Even with these subnormal price increases transformer sound levels have in general been kept equal to or slightly below the industry recommendations. The manufacturer has a great incentive to reduce the sound when using these newer core materials for, when he learns how to accomplish this, higher flux densities and still smaller transformers will follow.

The authors refer to exceptionally low level units that are built occasionally as if by accident. Our recent experience does not support this contention. The sound level of the completed transformer can be and is predicted with good engineering accuracy, and the variation between units is small. In fact, sound levels can be more accurately calculated than can exciting current. Under these circumstances a substandard sound level requirement inevitably involves a more costly transformer.

It is unfortunate that the authors could not present data on the effectiveness of shrubbery in reducing sound transmission, because this esthetically acceptable barrier should be welcomed in any residential area. The data on masonry walls and steel panels are a valuable addition to the meager information available concerning these barriers. However, the variation of attenuation with source intensity shown in Figure 18 of the paper gives rise to question. Perhaps this variation could be due to differences in spectrum with level, or to obscuring influence of the outside ambient level. The authors' comments on this point would be welcome.

I. S. Mendenhall and **F. L. Taylor:** Mr. Peck's discussion indicates that other utilities are facing the same transformer noise problems that were discussed in the paper. It also points out many of the disadvantages of installing sound barriers in connection with the installation of noisy transformers in residential areas. Most of these disadvantages are economic in the ultimate analysis, and indicate the need for studies of the costs of minimizing transformer noise by various means, including changes in the design by the manufacturer, use of different core materials, and the construction of enclosures or sound barriers by the utility.

It would be ideal, as Mr. Peck suggests, to have all transformers, regardless of size, so quiet that no sound barriers would ever be needed at any location. In the present state of the art, however, it is apparent that the cost of building one of the larger transformers of, for instance, 10,000-kva capacity so that it would have a 50-decibel sound level would be prohibitive.

Mr. Gordy offers several possible explanations for the variance of the data in Figure 18 from other published data. The curves were drawn from readings taken at several different locations, as he suggests. All of the data that entered into the drawing of each curve, however, were obtained from locations where the walls were between 18 and 20 feet in height, of the same thickness, and enclosed essentially the same space. Furthermore, most of the attenuation values were obtained from sound level readings that were taken about one foot inside the panel and one to four feet outside.

No measurements were made of the frequency composition of the noise. It is recognized that the attenuation afforded by a given panel will vary with the frequency and this may account for the unexpected behavior of the curves. Each curve is the result of a considerable number of tests, however, which it was thought would average out the frequency effect. It is planned to study the frequency composition of the sound when further tests of this kind are made.

Mr. Maslin points out that the new transformers are superior to the old in size, weight, and cost in comparison with other items. The utilities appreciate these advantages, and urge the manufacturers to continue the attack on transformer noise as vigorously as on other design problems.

It is thought that some manufacturers have difficulty in designing a new transformer for a definite sound level. As an example, the Detroit Edison Company since 1946 has purchased transformers of from 2,500- to 10,000-kva capacity, some of which had sound levels up to 8 decibels above the industry standard for the respective sizes of units. Fortunately this condition is not general and most manufacturers seem to be able to design to closer limits than this, although the noise levels are not as low as we would like.

The possible effects of the frequency composition of the noise on the curves of Figure 18 have been discussed in the foregoing. All noise tests were made late at night and every effort was made to take readings only when the ambient noise was at a minimum. It is thought, therefore, that ambient noise was not a factor in the results indicated by Figure 18.

In closing, the authors wish to express their appreciation to the discussors for their interest and many pertinent suggestions. It is hoped that further attention will be given to this problem by the engineers of both the utilities and the manufacturers, to the end that it may eventually be solved most equitably for all.

Locomotive Wheel-Slip and Wheel-Lock Protection

R. M. SMITH
ASSOCIATE AIEE

CERTAIN characteristics of the diesel-electric locomotive emphasize the importance of wheel-slip and locked-axle protection. This presents an important problem. The first step in its solution is an analysis of the fundamental phenomena of wheel and rail contact. This is supplemented with a study of tests made on locomotives in service. Together, they form a basis for setting up the requirements for a complete scheme of locomotive wheel-slip detection and protection.

Locked-Axle Problem

Accidents have occurred within recent years because of the locking of driving axles on diesel-electric locomotives, as reported in the minutes of the eleventh annual meeting of Locomotive Maintenance Officers Association, September 19–22, 1949. In some instances, the traction-motor armature bearings locked, and in others, the motor-suspension bearings on the axle locked. In some cases, the motors had been electrically disconnected from their generators, thus making the wheel-slip protective feature inoperative.

Various thermal devices have been suggested to detect overheated bearings before they lock. The relative inaccessibility of the bearings, their large number, and the desirability of furnishing protection against a locomotive starting with a locked (but cold) bearing, have made it seem more desirable to use axle speed rather than bearing temperature as a basis of detection.

High-speed wheel slip is one cause of locked armatures. A system of protection to measure and warn of differences between locomotive speed and axle speed would detect this. Necessary corrective measures could then be taken, either automatically or by the engineer, in time to prevent a locked axle developing from this cause.

Need for Wheel-Slip Protection

The diesel electric locomotive appears to require a degree of protection against wheel slip, never felt necessary in straight electric or steam locomotives. Recently the discovery of wheel slip occurring at speeds over 60 miles per hour has aroused new interest in detection systems of an inclusive character. The reasons for having a complete wheel-slip detection system are:

1. To prevent excessive traction-motor and locomotive speeds.
2. To allow the operator to detect slip on trailing units which are out of normal hearing distance.
3. To obtain optimum locomotive performance, that is, tractive effort, at all speeds.
4. To prevent derailment due to locked axles.
5. To prevent false forward transition.
6. To prevent wheel slide during braking.

Types of Wheel Slip

Wheel slip may be divided generally into two classes: those cases which occur at 20-miles per hour or less, and those which occur at higher speeds. At low speeds, it is possible for the motor torque to give tractive-effort levels greater than the weight on the locomotive axle multiplied by the normal factor of adhesion. At some speed around 20-miles per hour (depending upon the torque characteristics of the motor under consideration) the motor torque falls to a level such that the factor of adhesion must be greatly reduced in order to precipitate wheel slip.

Under very favorable conditions, factors of adhesion of 40 per cent at speed have been observed. Under very adverse conditions, factors as low as 4 or 5 per cent occur at standstill. These, however, represent extreme cases and occur because of some unique rail conditions. Only general causes of wheel slip will be discussed.

Causes of High-Speed Wheel Slip

It is commonly assumed that a locomotive driving wheel in motion, but not slipping, has a static friction lock with the rail and that when this friction lock is broken, the factor of adhesion drops very rapidly as slip increases. That this is not altogether an accurate picture can be seen from the curve of adhesion versus rate of slip, Figure 1.[1] If the curve of adhesion values is continued back to zero slip, a value of about 22 per cent is obtained. It is well known that in starting, values of 25 per cent with dry rail are normally obtained and values of up to 40 per cent can be reached under special conditions. Why, then, must the high-speed rolling friction given by this curve

Figure 1. Adhesion versus slip velocity

Paper 50-181, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted March 14, 1950; made available for printing April 26, 1950.

R. M. Smith is with the General Electric Company, Erie, Pa.

Figure 2. Driven wheel rolling on rail

be less? This is due to the fact that a rolling wheel always has a small amount of slip associated with it.

Consider for a moment a wheel as shown in Figure 2. As torque is applied about the center, *o*, the sections *AB*, *BC*, and *CD* are under compression, whereas sections *DE*, *EF*, and *FG* are under tension. A sketch of the area of contact, shown in Figure 3, reveals that the front section of the area is under compression whereas the rear section is actually under tension. The fact that part of the wheel tread is under compression requires that the wheel make more revolutions per mile than would be indicated by simply considering the distance moved per revolution as the circumference of the wheel. This factor[3] may be calculated as follows

Forces at the point of contact =

$$\frac{\text{coefficient} \times \text{velocity of creep}}{\text{velocity of roll}}$$

If a steel wheel is considered, a representative value of the coefficient equals

$$3{,}500 \sqrt{\text{diameter of the wheel (inches)} \times \text{weight on axles (pounds)}}$$

For the purpose of illustration, assume a 50-inch wheel and 50,000-pound axle loading. If the rail and wheel were in a static lock, which we are attempting to show is not true, we could expect to develop 12,500-pound tractive effort. The coefficient now equals 5,530,000 and the velocity of creep equals 0.227 per cent. Thus, the locomotive in moving one mile actually causes its wheel to rotate 1.00227 miles.

A second factor, indicating that the rolling condition is actually one of small slip, is the taper applied to the wheel tread. Curves or irregularities in the track cause the wheels to move laterally on the rails from one side to the other. If the flange on one wheel is against the rail, then the opposite wheel must be running on a circle of smaller diameter, hence one of the wheels must slip as the axle moves to center itself. Note that the degree of this inherent slip is dependent on speed and that at lower speeds higher factors of adhesion are more common.

The tractive effort characteristics of a diesel-electric locomotive are shown in Figure 4. This curve cannot be expected to match the change in the factor of adhesion shown in Figure 1. If a wheel can be accelerated enough to move onto the sharply decreasing portion of the factor of adhesion curve, and no change in friction characteristics takes place, the wheel will accelerate until a new balance between the torque characteristics of the motor and the friction characteristics of the wheel takes place. This represents an idealized case and will occur only in unusual circumstances when track conditions and axle loadings remain constant. That this is possible, however, is shown by Figure 5, taken from track tests on a gas-turbine electric locomotive in which the axle accelerated and then stabilized itself at a speed approximately 13-miles per hour greater than the running speed. A more common type of slip is for the wheel to vary widely in speed as the action of the truck equalizers alters axle loadings.

Additional Factors Causing Slip

At high speeds, there are a number of factors which, singly or in combination, can cause the weight on the driving axle to be reduced momentarily. These same factors are present on steam and electric locomotives, but because of the greater inertia involved, the slip does not have time enough to reach a value at which the factor of adhesion is seriously reduced. Among the factors which can cause a temporary reduction in the weight on a driving axle are:

1. Unbalance in the driving wheel itself.
2. Eccentricity of the driving wheel.
3. Irregularities in the track, particularly switch frogs and crossings.
4. Journal boxes cramped in their guides.
5. Poor operation of the equalizers.
6. High gradient equalizer springs.
7. Weight shift.
8. Any vertical oscillation caused by resonance in the spring system.

It is very difficult to assess these factors quantitatively. For example, measured accelerations of 5 *g* to 13 *g*, *g* being the acceleration of gravity, have been obtained on the ends of axles moving through crossings at high speed. The duration of these accelerations is short, however, and by themselves they do not normally cause wheel slip. It is probable that a combination of the foregoing factors is necessary to cause high-speed wheel slip.

The other cause of high-speed wheel slip is momentary reduction of the factor of adhesion with constant axle loading. This may occur from changes in rail surface conditions caused by: mist or dew; mill scale occurring on newly laid rail; and oil, fertilizer, insects, wet leaves, and other foreign substances on the rail.

Low-Speed Slip

Low-speed slip can be started by either of the basic methods; that is by temporarily unloading an axle, or by decreasing the coefficient of adhesion. Dynamic factors such as wheel unbalance are insignificant. The subject of low-speed wheel slip, particularly the causes of low adhesion, has been reported elsewhere.

Detection of Wheel Slip

At present, there are available a number of schemes for detecting locomotive wheel slip. These are:

1. The detection of electrical unbalance between traction motors.
2. The measurement of residual motor voltage.

Figure 3 (below). Area of contact between driven wheel and rail

Figure 4 (right). Speed-tractive effort curve, 1,500-horsepower Diesel-electric freight locomotive

Figure 5. Oscillogram showing stable slip

3. The frequency-sensitive system.
4. Various acceleration schemes.
5. The axle-mounted commutator and brush system.
6. Individual axle generators.
7. The axle-mounted centrifugal switches.

Differential Voltage Detection

The one in most common use employs a relay connected as shown in Figure 8(A). This relay measures the unbalance in current which exists between traction motors during slip conditions. If one motor should speed up, its current drops, thereby unbalancing the bridge circuit and actuating the relay.

This system has the advantage of low cost, and since it measures electrical quantities, it is easily connected in the cab. It detects wheel slip, and a locked axle only when power is on. It does not detect overspeed, nor does it furnish locked-axle protection when the motor is disconnected.

Figure 8(B) shows the same type relay connected so as to measure differential armature voltage.

In both of these circuits the relay is subject to transient voltages due to current surges in the motors. These in turn are caused by changes in track surface causing relative movement between field and armature, commutation phenomena, and so forth.

In order to care for transient voltages and normal electrical differences in motors, it is necessary to make these relays comparatively insensitive. In the high-speed connection with shunted motor fields, relatively large speed differentials are required to operate the relay. The possibility of stabilized slips of 10 to 20 miles per hour over locomotive speed, plus the high differential required in the high-speed region make this system only partially effective. Moreover, it gives wheel-slip indication of varying sensitivity during acceleration and locked-axle protection only with power on.

Residual Motor Voltage Measurement

In conjunction with the system just described, there is a method of furnishing locked-armature protection by measuring residual motor voltage. A relay is connected across each traction motor armature. As long as residual voltage exists the relay is picked up. If, as in the case of a locked armature, no residual exists, this relay drops out.

One type of General Electric traction motor widely used on diesel-electric locomotives has a maximum residual voltage of 21.9 volts at 2,280 rpm. At 5 per cent speed, the lowest residual voltage is 0.5 volt. Thus, the relay measuring the residual must be able to operate on 2.05 per cent of the maximum voltage applied across it.

Actually, if power is taken off while moving, energy to pick up the relays comes partly from the inductive energy stored in the motor fields. If a locomotive should start with a locked axle, the protective relays could not be expected to pick up until a much higher speed was reached than that at which drop-out occurs. These relays provide locked-axle protection with power off. Occasional malfunctioning due to variations in residual voltage can be expected.

It would be possible to add a third set of relays to check on motor overspeed. Still others might possibly be included to cover rolling slip during braking (either air brakes or dynamic brakes). Such a system would offer complete protection by means of apparatus and connections entirely within the cab. The number of components required for complete wheel-slip, wheel-slide, overspeed, and locked-axle protection would be great and would probably result in unreliable operation under certain conditions.

An integrated system, independent of the traction motor power, is inherently more reliable for complete protection.

Frequency Detection

The Metropolitan Vickers Electrical Company, Ltd. has in operation one scheme in which an auxiliary pole-face winding is incorporated in the traction motor. The output frequency is then compared with frequency signals from the other traction motors.

This approach could be made to give complete protection. The high premium put on winding space within the traction motor, however, makes it unlikely that this scheme will be widely adopted in this country.

Figure 6. Oscillogram showing rapid rate of rise of wheel slip

Figure 7. Oscillogram showing slow rate of rise of wheel slip

Acceleration Measurement

Various acceleration measuring methods have been suggested. At least two such devices are in fairly common use on passenger cars to prevent slide flats during braking. Deceleration rates in this service are in the order of 25 miles per hour per second during wheel sliding. By contrast, rates of acceleration during locomotive wheel slip may range from 3 to 20 miles per hour per second as shown in Figures 6 and 7. Accelerations in the lower ranges would cause unreliable operation of such devices. In addition, starting a train with a locked wheel would obviously give no indication of acceleration. It is apparent, therefore, that a measurement of velocity is necessary.

Speed Differential Measurement

One device which could be adapted to measuring locomotive wheel slip consists of a fixed commutator and a rotating brush mounted on the journal box and driven by the axle. This device measures the difference in rotative speed between any two axles. It depends upon the improbability of any two axles slipping or sliding at the same rates. If the two axles being compared have their driving motors connected in series, this is very likely true. If two traction motors are connected in series across a fixed voltage, a speed-up of one motor will cause it to develop more than half the supply voltage across its terminals. This will be accompanied by a reduction in voltage and torque, shown in Figure 9, on the other motor. Although this voltage shift does not limit the acceleration on the slipping axle, it does insure that under ordinary rail conditions the second axle will not slip. The cost of this system is high compared to the differential relay protection commonly employed. It also is probable that there will be an appreciable maintenance problem on the commutator and brush rigging.

Figure 8. Wheel slip protection circuit

(A) Connected to measure unbalance in traction motor current

(B) Connected to measure differential armature voltage

Variations of this system would allow complete protection.

Locked-Axle Protection

There has very recently come onto the market another system known as the King wheel slide indicator which gives protection only against locked axles. This consists of axle-mounted centrifugal switches. As the locomotive reaches a predetermined speed, one of the axle switches (designated as the master switch) closes and applies power to similar switches mounted on all the other axles. If each of the other axle switches has tripped, indicating that all axles are turning, a light relays this information to the engineer. This device furnishes only locked-axle protection and must be coordinated with one of the other systems described in order to give complete wheel-slip protection.

Individual Axle-Generator Protection Scheme

The Alco-GE gas-turbine electric locomotive was built to study the application of a gas turbine to locomotive service. One of the factors under observation was the wheel slip characteristics of the unusual axle arrangement. The system installed consisted of individual axle-mounted generators, of the same type as those used for controlling transition on Alco-GE locomotives, with a relay to detect the difference in voltage between each generator and the average for all eight generators. Specifications were that the system should operate on a speed differential of 5 miles per hour. This was to allow for normal differences in wheel diameter. Since the generators are of the permanent-magnet type, the system is independent of any locomotive power supply. It is possible to protect against motor overspeed by measuring the absolute value of generator voltage. This system answered the requirement of furnishing complete protection, but the cost of the axle generators makes its widespread use doubtful.

Requirements for Complete Protection

A study of the oscillograms of actual slips obtained on the Alco-GE gas-turbine electric locomotive and also diesel-electric switchers and road locomotives allows a consideration of the deficiences existing in the present methods of wheel-slip detection and makes it possible to draw up a tentative set of specifications for a complete wheel-slip protection system. The system should furnish four types of protection: (1) wheel-slip protection during acceleration; (2) wheel-slip protection during braking (air or dynamic); (3) locked-wheel protection; and (4) overspeed protection.

At low speeds, the protective devices should operate at speed differentials of about 5 miles per hour. At speeds of 40 miles per hour or greater, the allowable slip should be increased to permit a slip equal to 10 to 15 per cent of locomotive speed. The reason for this tapering of sensitivity at higher speeds is to allow self-recovery due to changes in rail condition. It has already been pointed out that starting of high-speed slip is usually a transient phenomenon. Therefore, if normal rail conditions are restored, wheel slip will often stop without requiring corrective action, with its attendant loss in tractive effort. In any case, if the rate of rise should exceed 10 miles per hour per second, corrective action would be taken regardless of the actual speeds involved. A study of the various oscillograms taken reveals no case of recoverable slip occurring at acceleration rates greater than this. Before locked-axle protection can function, the locomotive must attain some finite speed sufficient to determine that an axle is actually locked. A fair compromise for this figure seems to be 5 miles per hour.

During dynamic braking, it is desirable to be able to load each wheel up to the maximum available factor of adhesion. If the traction motors are properly connected, it is not possible to lock wheels during dynamic braking because at zero speed, the power output of the motor is zero. The fact that there is little likelihood of damaging the traction motor or the wheels during small values of slide in

Figure 9. Torque loss on series-connected motors

dynamic braking, coupled with the desire to get maximum braking effort from the locomotive should allow higher values of permissible slide to be established. A value may be tentatively set at 20 per cent of the locomotive speed or 10 miles per hour, whichever is higher.

The overspeed feature of the system should be set at whatever value the manufacturer recommends for the motor with which the locomotive is equipped.

The correction initiated by such a wheel-slip scheme should be automatic and should be limited to the unit affected. In any practical control scheme requiring action by the engineer, he can only correct slipping on any one unit by reducing the power on all. The resultant loss in tractive effort is undesirable. In overspeed, the time lag occurring between the signal to the engineer and the actual reduction in power could be great enough to allow permanent damage to the motor, hence the requirement for automatic correction. A cab indication of slip is necessary to warn the engineer of repeated slips so that he can reduce power. Locked-axle protection definitely requires a cab indication.

Two approaches to this problem exist. One is to add more devices to the schemes already used to provide partial protection. The other is to develop one integrated system for the whole protective function.

Modifications to existing systems have been made by several railroads, and these are now undergoing tests. The idea of a single protective system has been tried on a much smaller scale. Only further experience in actual service can prove the superiority of either of these two approaches.

A New Resilient Class-H Material for the Insulation of Traction Motor Field Coils

J. ROSS REED
MEMBER AIEE

J. J. TYNER
NONMEMBER AIEE

THE rapid shift by the railroads of this country to the diesel-electric locomotive as standard motive power and the consequent tremendous increase in heavy d-c traction equipment has brought to the fore many problems to vex both the designers of the original equipment and the maintenance men who must keep it in economical operation. Among these problems is that of finding electrical insulation for traction motors which will withstand for long periods of time the rigors incident to the severe conditions of operation encountered in railway service. Much has already been done to develop and utilize electrical insulating materials with a high degree of thermal stability, and class-*H* materials[1] are now standard on a large percentage of traction motor armatures in service. Class-*B* materials,[1] however, are still universally used for the insulation of traction motor field coils, and their shortcomings for this application contribute heavily to the cost of maintenance in this class of equipment. This paper describes the development and application of a new resilient class-*H* insulating material which is being used successfully on field coils by at least one of the major American railroads.

Standard class-*B* materials are not best suited to meet the conditions of service imposed on high-speed railway traction motors. In the first place, temperatures are normally encountered which reduce the effective life of these materials to a point where they soon constitute a weak link in the chain of components making up the present-day traction motor. As the life of the electrical insulation is spent, the coils become progressively more vulnerable to the effects of shock and vibration which are an inescapable part of railway service. Any shrinkage of the insulation allows relative motion between the coils and the pole-piece mountings. This movement of the coils soon produces abrasion of both the insulation and the pole piece or coil support flange itself. Figure 1 illustrates a typical example of the results of loose field coils abrading the metal flange on which the coils are secured.

In addition to promoting looseness of the coils, this loss of life in the insulation is accompanied by a serious increase in brittleness and resultant decrease in resistance to abrasion. Thus, a vicious circle of events is produced and electrical failure of the insulation is the inevitable result. To make the situation even more serious, the insulation cracks as it becomes brittle. This allows conducting contaminants, such as carbon dust and moisture, to permeate the insulation and destroy its effectiveness as a dielectric protection for the electric conductors in the body of the coil.

The use of class-*H* materials for the insulation of field coils of many types of motors has been practiced successfully for a number of years. Conventional class-*H* insulating materials give adequate protection against heat and provide a long life insulation for the average motor in the commonly encountered conditions of severe industrial operation. Here the problems of severe shock and high-amplitude vibration are of relatively minor importance. Under these conditions, a hard finished coil, which will maintain its rigid dimensions for long periods of time at high temperature, is satisfactory.

When the need for better insulation on field coils in heavy traction motors was evident a number of years ago, several sets of fields were fabricated to class-*H* specifications in accordance with the standards used for general industrial motors. Rigid coils of the type mentioned previously were manufactured and installed in test motors which were placed in high-speed passenger service for actual road testing. The results of these tests have been highly satisfactory and show conclusively that these coils have much to offer over the standard class-*B* coils for this type of service. One of the test motors equipped with these fields now has in excess of 750,000 miles of service to its credit. The fields of this motor at the last shopping showed no apparent deterioration after 742,000 miles of service. All of the coils were still tightly seated and the insulation was still pliable with no signs of external cracking.

The condition of the coils contrasts strongly with that of standard field coils in the same type motors operated under the same conditions. The average insulation life for standard coils is between 500,000 and 600,000 miles. After that amount of service, the external ground insulation of the coils is dry, brittle, and cracked, and usually must be replaced for further service.

Though the type of class-*H* coil described has definite advantages over the standard class-*B* insulated coils, even in railway applications, it was evident that coils with greater inherent resiliency would offer still further advantages in such service. Because of the unusual properties of silicone rubbers, experiments were initiated to determine if some member of this general class of material might

Paper 50-182, recommended by the AIEE Land Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Figure 2 (right). Thermal conductivity of Silastic versus silicone varnish impregnation

be adaptable to this application. It was obvious that a coil mounted between rubber "springs," which would maintain their resilience for long periods of time at high temperatures, would be more easily tightened in place and made to remain tight than would a rigid coil, which must of necessity be built to very close mechanical tolerances to obtain a tight fit. It also was recognized that silicone rubbers possessed several other properties which indicated unique suitability for this application. These materials have found wide industrial application because of their chemical resistance, high thermal conductivity, extreme moisture resistance, and good dielectric properties, along with the fact that they maintain these properties over a temperature range from −70 degrees Fahrenheit to 500 degrees Fahrenheit.

Silicone rubbers have dielectric properties comparable to the best resilient insulating materials at room temperatures and far superior to them at high temperatures.

Unlike resinous coatings and insulating materials, these rubbers do not become progressively more brittle at high temperatures and have virtually unlimited life at 400 degrees Fahrenheit. Silicone rubbers have exceptional resistance to electric arcs and flashes even under conditions of high humidity, and give a surface that will not carbonize to produce a resultant low-resistance track.

In addition to these properties, silicone rubbers have characteristically high thermal conductivities as compared to resin-bonded insulating materials. Curves showing this relationship are given in Figure 2. From this it may be seen that a coil insulated with silicone rubber will operate about 15 per cent cooler than a comparable coil insulated with resin-bonded materials. Thus, the temperature resistance of silicone rubber is augmented by the lower temperature of operation of coils insulated with it, as compared with standard insulated coils operated under the same conditions. This will, of course, still further increase the life expectancy of such a coil.

To adapt a silicone rubber for use as insulation on field coils, it was necessary to produce the materials in such form that it could be easily applied to form a sealed sheathe around the coils. It was recognized that this covering must be continuous, leaving no openings that would admit moisture or other contamination. The use of silicone rubber in paste form was considered and rejected because of the many mechanical difficulties involved. To apply the silicone rubber in a precured form introduced the equally serious problem of sealing any joints which would be formed. After considerable experimentation, it was decided that a pressure sensitive tape would be ideal to form a solid mass of insulation, free from voids and unsealed joints. A Silastic tape was developed that consisted of Fiberglas cloth coated and impregnated with silicone rubber. On one side of this tape the silicone rubber is completely cured, while on the other side, it is only partially cured and remains tacky, subject to subsequent vulcanization. This material proved admirably suited for application to field coils and other rigid sections. The presence of the reinforcing glass fabric gives the tape sufficient strength to allow considerable tension in application without any appreciable reduction in thickness or other mechanical distortion. Actually, the 20-mil tape, as finally developed, has a tensile strength of 80 pounds per inch of width, while a similar tape 12 mils in thickness has a tensile strength of 60 pounds per inch of width.

This tape can be vulcanized and cured in an air-circulating oven, or even in use, if operating temperatures are sufficiently high, although this latter method is not suitable for field coil applications where compressive strength is required at the time of application of the coils to the motor frame. Actual curing time, of course, will vary with the mass of the unit taped and with the thickness of the taped section. However, satisfactory vulcanization of the tape can be obtained in 15 minutes at 260 degrees Fahrenheit after the materials have attained that temperature. Following the initial vulcanization, it also was found desirable to give the tape an after cure in an air-circulating oven at a temperature above the maximum operating temperature of the coil, or at 350-400 degrees Fahrenheit, whichever is higher.

To produce complete vulcanization of the tape into a solid mass, it also was found that pressure between laps was desirable in addition to that obtained in taping. This was easily accomplished by covering the Silastic tape with a tightly pulled serving of glass tape prior to vulcanization.

The relative abrasion resistance of a section taped with this material compared to organic bonded Fiberglas is well illustrated in Figure 3 In these tests, similar sections were taped with the two materials and subjected to a sandblast for periods of 6 seconds with results as shown.

Further tests were run to determine the effects of continuous immersion in an aqueous solution. Figure 4 shows the effect of immersion in salt water for a period of 40 days on the insulation resistance of this material.

Built-up sections of this tape showed a minimum consistent dielectric strength of 300 volts per mil in the cured condition with two layers of 20-mil tape. Surface resistivity after 24 hours at 50-per cent humidity was in excess of 10^{15} ohms. After 96 hours at 96-per cent relative humidity surface, resistivity was still in excess of 10^{16} ohms. Volume resistivity

Figure 3 (left). Relative abrasion resistance of Silastic insulation and organic varnish treated Fiberglas tape

Figure 5 (right). Main field coil for traction motor insulated with silicone rubber

after 24 hours at 50-per cent humidity was in excess of 10^{13} ohms-centimeters and was in excess of 10^{10} ohms-centimeters after 96 hours at 96-per cent relative humidity.

Following the development of this tape and the determination of its general characteristics and properties in the laboratory, a number of test coils was insulated. This was done to determine the best methods of application to both new equipment and to equipment which was to be reinsulated after previous service, as well as to give a practical basis for further physical tests and cost estimates. In many applications, particularly on new coils, it is thought that this type of tape can well replace all standard types of insulation. However, the elimination of all mica from standard traction motor field coils seemed too radical to be readily accepted without conclusive tests and operating experience. In addition to this, the reinsulation of field coils where the standard organic bonded turn insulation is not to be disturbed presents another problem. Organic materials, or even uncured silicone varnishes, in contact with Silastic tape will seriously inhibit its vulcanization. Where these materials are inherent in the coils being taped, some sort of a shield must be provided to separate them from the Silastic tape. Silicone bonded Mica-glas tape is well suited for this application and gives an additional dielectric build-up to the total insulation.

Taking into consideration all of the foregoing factors resulted in the following general specifications for reinsulation of a typical traction motor field coil, previously cleaned and stripped of old insulation. The coil first is dipped in silicone varnish and allowed to drain and air-dry until the varnish is tacky. Following this, the coil is taped entirely with a butt-lapped serving of 10-mil glass tape that previously has been treated with silicone varnish for ease of handling. This glass tape serves as a protection between the bare copper and whatever mica is placed next on the coil. For our experiments and subsequent production we have used a one half-lap serving of 7-mil silicone-bonded Mica-glas tape as the next element in our build-up. This is followed with a no-lap serving of 10-mil glass tape to draw the mica down and to reduce the voids.

Figure 4. Silastic winding insulation resistance after immersion in salt water

Following these three servings of tape, the coil is heated to 200 degrees Fahrenheit and hot-dipped in silicone varnish for 5 minutes and allowed to drain before baking at 300 degrees Fahrenheit for 3 hours. At this stage of the build-up the insulation is securely bonded with silicone resin and is well compressed into a solid mass relatively free of voids. All volatile solvents have been expelled and the organic materials in the body of the coil have been sealed off effectively so as to preclude any interference with the subsequent vulcanization and cure of the Silastic tape. In addition, there is a solid base over which the Silastic tape may be pulled tightly to give a relatively high pressure between servings.

At this point, pads of silicone rubber are placed on the prospective bearing surfaces to give enough dimensional build-up so that the completed coil will meet specifications in this respect. Silicone rubber paste may be spread on the coil at this stage of the build-up to further fill in any low places and to help strengthen the bond between the silicone-bonded mica and the Silastic tape, which is next applied as a half-lapped serving over the entire coil. It is suggested that a 20-mil tape be used for this purpose and that care be taken to apply it uniformly and with as much tension as is practicable. The thickness and amount of this tape can be varied depending on the amount of resilient material desired in the total build-up. A final serving of 10- or 15-mil glass tape is used half-lapped to increase the pressure between servings of the Silastic tape and to give added mechanical protection to the silicone rubber.

The coil should then be placed in a 300-degree Fahrenheit oven for 1 hour to vulcanize the Silastic tape. It is then hot-dipped in silicone varnish and baked for 12 to 16 hours at 300 to 400 degrees Fahrenheit. The higher temperature is preferable if the materials of which the leads are made will not be injured, although satisfactory cure can be obtained even as low as 300 degrees Fahrenheit. The baking time will vary inversely with the temperature of the cure, which should in any event be higher than the highest operating temperature expected in service.

Coils were insulated to the foregoing general specifications and tested in the laboratory to determine their physical characteristics. A typical coil thus insulated is shown in Figure 5. Dielectric tests were made by clamping metal plates to the surfaces of the coils and applying test voltages while these plates were under pressure. An average breakdown strength of 20,000 volts was determined at room conditions in this manner.

Additional tests were made on this insulation build-up to determine the degree of compression-set that might be expected in service. At a pressure of 40 pounds per square inch, no compression-set could be determined after 2 weeks at 380 degrees Fahrenheit. On a total Silastic build-up of 64 mils thickness, a compression-set of 1.2 mils was produced by a continuous pressure of 75 pounds per square inch for 2 weeks at 380 degrees Fahrenheit. During this time the resiliency of the material was not altered measurably.

Cost estimates at this time indicated that the build-up described would be attained at a figure in a comparable price range to standard class-*B* insulation.

In order to determine the results of actual road service on this type of insulation, one of the larger railroads was approached with the results of the laboratory tests and the cost figures which had been determined. A total of more than 1,300 field coils has been reinsulated in this manner and have been placed in regular service without a single failure of any kind to date. It is not possible at this time to give ultimate life statistics for this type of insulation on the basis of actual service simply because not enough time has elapsed yet for their complete determination. However, from the service indications which we now have, it is confidently expected that loosening of field coils in railroad service and consequent movement on pole pieces will be entirely eliminated.

With this major cause of field coil troubles eliminated, the insulation life expectancy of this class-*H* build-up as compared to other types of insulation for various temperatures should conform to the curves given in Figure 6. Certainly at the temperatures at which traction motor fields are often operated, the life expectancy of this insulation should be many times that of the class-*B* materials now accepted as standard.

Additional tests are being conducted to determine the effect of complete elimination of mica, for example, in new coil construction where there is no need for blocking off the organic materials as there is when old coils are being reinsulated. If this proves feasible, as is indicated at present, there may be some savings over presently-accepted standards of field coil insulation.

On the basis of the tests at the laboratory level and the results of regular production and road service, there seems little doubt that silicone rubber offers a much-needed solution to the problem of keeping traction motor field coils tight over long periods of time at elevated temperatures of operation. In addition to this, it offers all the advantages of class-*H* construction at a cost comparable to that of standard class-*B* construction in a coil which actually will operate at a substantially lower temperature than its class-*B* counterpart under the same conditions of operation.

Effect of Frequency on Perception Currents

CHARLES F. DALZIEL
MEMBER AIEE

THOMAS H. MANSFIELD
ASSOCIATE AIEE

Synopsis: The predominating sensation produced by gradually increasing direct current is warmth in the palm of the hand or wrist. Sensations caused by alternating currents below 10,000 cycles are characterized by a tingling or pricking sensation which is localized in the area adjacent to the point of contact, and at very low frequencies the muscles tend to follow the alternations of the current waveform. For frequencies between 10,000 and 100,000 cycles, the sensations are similar to those at the power frequencies, but they are less intense, and perception occurs over larger areas around the point of contact. An abrupt change in the response occurs between 100,000 and 200,000 cycles when the sensation becomes one of internal heating, and heating is believed to be the only sensation produced by currents in excess of 200,000 cycles. The current required for perception increases with increasing frequency, and between about 1,000 and 100,000 cycles the current is nearly proportional to frequency. Approximately 150 men were used in these investigations and it is believed that a sufficient number were used to permit valid statistical predictions to be made, not only for the particular group tested, but also for a normal cross section of the adult male population of the country.

ELECTRIC currents which are just perceptible are important, as it is essential that the user not get the sensation of electric shock when using electric appliances, hand tools, or other electric equipment.[1] Shocks produced by currents near the threshold of perception are generally considered annoying rather than dangerous; however, when such shocks are unexpected, they are startling, and serious accident may result as a secondary effect. For example, an unexpected electric shock, far too feeble to cause injury due to direct effects of the electric current, might produce a sudden movement and cause subsequent contact with a dangerous mechanism, or it might cause loss of balance with an ensuing fall which might cause painful injury.

The investigations reported in this paper were undertaken to expand the knowledge of the effects of electric current on the human body by observing the phenomena of perception under several contact conditions for direct current and for sine-wave alternating currents from 60 to 200,000 cycles per second. The experiments were conducted in the electrical engineering laboratories of the University of California at Berkeley, during the academic years 1940 and 1948–49. Four women and 143 men participated in the investigations.

Only subjects apparently in good physical condition were used in the study, and only those parts of the skin which were free from cuts and abrasions were subjected to quantitative tests. Moist contacts were used in the investigation to minimize the range of contact resistances, and to permit the use of low voltages for safety. As a result of the low voltages employed only minute sparks were produced when the subject interrupted the current. Care was exercised to avoid causing burns at the points of contact with the body, and although burns are extremely important, of necessity this subject was not investigated. It is entirely possible that arcs might occur with commercial apparatus at the higher perception current levels corresponding to the higher frequencies, and these arcs might cause painful burns, especially if sustained for a considerable period of time.

The subject sat in a relaxed position in a chair so located that he was facing away from the test equipment. After the subject was prepared for the test, he was told that the operator would slowly increase the current, and he was asked to report when the first sensation was observed. When the subject perceived the current, the increase in current was stopped, and the magnitude was noted. The current was then decreased to zero in preparation for another run. One or two trial runs allowed the subject to become acquainted with the testing procedure and the sensations resulting from the frequency being investigated. Three or four determinations of the minimum current perceived with slowly-increasing current were then made and the values were recorded. The results of the trial runs were not recorded, as the purpose of these runs was to acquaint the subject with the sensations involved at each frequency. This technique yielded a conservative value, as the current required for perception in the first determination for each subject at any frequency was generally somewhat higher than subsequent values.

Throughout this investigation an individual's threshold of perception at a given frequency is taken as the mean value of current just causing sensation when using a subthreshold approach. The threshold of perception for a group is taken as the mean value of the group. The current likely not to be perceived is taken as that value of current which is detectable by only 0.5 per cent of the group, and the upper limit of perception current is taken as that current perceived by 99.5 per cent of the group.

Aside from physiological factors which were beyond the control of the investigators, five factors are important in determining the current which can just be perceived. These factors are: point of contact; type of contact; rate of increase

Paper 50-184, recommended by the AIEE Safety Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted October 31, 1949; made available for printing April 25, 1950.

CHARLES F. DALZIEL is Professor of Electrical Engineering, University of California, Berkeley, Calif., and THOMAS H. MANSFIELD is Electrical Engineer with Tracerlab Inc., Berkeley, Calif.

Acknowledgment is given Spencer H. Robley who, in 1940, obtained the experimental data for the group of 115 subjects. He was senior student in electrical engineering, University of California, Berkeley, at the time the study was made.

Figure 1. D-c perception distribution curve for hands holding number 7 copper wires

Figure 2. 60-cycle perception current distribution curve for hands holding number 7 copper wires

Figure 3. 60-cycle deviation curve for hands holding number 7 and number 8 copper wire electrodes

of current; frequency, and wave form.

Inasmuch as the point of contact with the skin has considerable effect on the level of the current required for perception, it is obvious that a great many different perception thresholds could be investigated. Considerable thought was given to this phase of the problem, and it was decided to concentrate on the hand and fingertips, since contact with the hands is responsible for many of the complaints caused by electric currents near the perception threshold. Preliminary tests were made on the tongue, and although the results of this threshold are of minor practical importance, comparison with the results obtained on the hands emphasizes the range of values for different points of contact on the body.

Three types of contacts were used. These consisted of holding, touching, and tapping test electrodes. In the holding contact tests, a smooth wire or wires were held in the palms of the hands or placed lightly on the tongue. For the touching contact tests, the middle finger was placed lightly on a polished flat copper plate. In the tapping contact test, the middle finger tapped the copper plate at a rate of once to twice a second. Two identical electrodes were used in the first series of tests. In the second series the circuit was completed by an indifferent electrode, consisting of a flexible lead strip wrapped with gauze soaked in salt solution which was clamped around the upper arm.

The magnitude of the current, accommodation effects, and the effect of frequency and wave form on perception will be discussed later in the paper. In the first series, tests were made on 115 men, using direct current obtained from batteries, and commercial 60-cycle alternating current. For subsequent tests, made on 28 men and four women, the a-c power supply consisted of a Hewlett-Packard model *200C* audio-frequency oscillator and a power amplifier. The output was continuously monitored with a Dumont model *208B* cathode-ray oscilloscope, and care was exercised to maintain sinusoidal waveshapes.

General Observations

In addition to the numerical data, certain phenomena were observed relative to the sensations caused by the passage of electric current through the hands. These observations are of assistance in interpreting the quantitative results of the investigation, and will be discussed prior to presentation of the experimental results.

At the outset it was planned to establish the perception current on the hands with both gradually increasing and decreasing currents in anticipation that this procedure would yield an accurate determination of the threshold of perception for a given frequency. However, it was found that when the current was adjusted to a value slightly greater than an individual's threshold of perception, and was then gradually decreased, erratic values were obtained and the subject reported difficulty in determining when the sensation actually ceased. A particular individual might report that he thought the sensation had ceased at current values varying from slightly above his perception value for gradually increasing current to a current of approximately one-half of this magnitude. Results of the tests performed with decreasing current were so variable in comparison with the close agreement of the individual's response at a particular frequency with increasing current that little information of practical importance appears to be gained from this type of test. It was hoped that some observations attributable to aftereffects, or to accommodation processes, might be explained using the intended technique, but the great variation in the reported values prohibits the drawing of worth-while conclusions. The original plan was abandoned, and except for a few preliminary tests, a subthreshold approach was used throughout the investigations.

For tests using frequencies of more than approximately 30,000 cycles, it was observed that the rate at which the current was increased had an appreciable effect on the current level at which perception occurred; in contrast, the perception current at lower frequencies appeared to be independent of the rate at which the current was increased. For higher frequencies, as the current was increased at faster rates the subject reported the presence of sensations at successively lower levels of current. As a result, an attempt was made to approach the higher frequency thresholds at a rate of current increase of approximately 3 to 6 milliamperes per second. Varying the rate at which the current was increased to roughly 75 per cent of the threshold value failed to produce appreciable variations in the threshold provided the remainder of the approach was made at the established

rate; consequently, this procedure was followed to save time and reduce fatigue.

The phenomenon of accommodation at the higher frequencies again manifested itself in the touching and tapping contact tests. In this instance, the value of current just perceived when tapping the copper plate was considerably less than the current required for perception when touching the plate with gradually increasing current. When the energized plate was touched and contact was maintained many subjects reported an initial sensation that faded away in several seconds. The time required for the sensation to fade away seemed to be a function of the intensity of the initial sensation. Quantitative determination of this interval was not attempted because of the difficulty of determining the moment that sensation ceased.

Several subjects reported that they were able to draw slight sparks from the copper plate when the contact was broken during the tapping contact tests at the higher frequencies. The minuteness of the pin-point burns caused by these sparks, which were not visible in a normally lighted room, is attributed to the fact that the voltage used in these tests was sufficient to maintain a spark for only a very short period of time as the finger moved away from the electrode. The open circuit voltages employed varied between about 20 and 100 volts; maximum current was about 112 milliamperes.

Several times during the holding contact investigations the subjects reported a definite sensation when they released the electrodes while a current slightly below the perception level was flowing. The same phenomenon was reported by several subjects when the circuit was interrupted by the operator. However, the phenomenon did not occur with sufficient regularity to permit determination of its cause.

Included in subsequent paragraphs are generalized comments on the sensations produced by currents about 25 to 50 per cent above the perception value.

As would be expected, the sensations caused by direct current are different from those occurring when alternating current is applied. Except when the current is changed suddenly, muscular contractions are absent. If the surface of the skin is intact, the first sensations are those of slight warmth in the palm or in the wrist, and these sensations are quite difficult to detect. If the surface of the skin has minor defects, sharp piercing sensations are produced with very low currents.

The outstanding feature of the sensations in the power frequency range is the sharpness of the sensation when the perception current is exceeded. This sensation is variously described as a tingling or pricking sensation at the point of contact. Many of the subjects also observed this sensation under the indifferent electrode. This effect was not reported at frequencies in excess of 1,000 cycles. The presence of sensation at the indifferent electrode was attributed to the presence of small imperfections in the surface of the skin under this electrode, and was probably due to high-current densities at tender spots, but no explanation is offered for its disappearance at the higher frequencies. At very low frequencies (5 to 20 cycles) the muscles of some of the subjects were observed to follow the alternations of the current wave form, however, insufficient data were taken to establish the threshold at these frequencies.

As the frequency was increased, the intensity of sensation caused by currents slightly greater than the perception value decreased. For frequencies between 1,000 and 10,000 cycles, the subjects commented that the sensation was smoother, softer, and less piercing than that caused by 60-cycle currents, and that it seemed to spread from the area in immediate contact with the test electrode to a greater part of the hand. Several subjects stated that currents having frequencies near 10,000 cycles caused a sensation similar to that observed when the hand "goes to sleep."

Currents of frequencies between 30,000 and 90,000 cycles were reported to give an increasing spread of sensation away from the test electrode, and to cause a sensation of drawing of the skin or of a pressure on the hand. As the frequency increased, the sensation was less intense.

The touching and tapping contact tests using frequencies between 100,000 and 200,000 cycles brought forth the opinion from all subjects that the sensation caused by the higher frequencies was one of heat rather than of the muscle stimulation noted at the lower frequencies. After the subject had reported this change in sensation, an attempt was made to determine the frequency at which the change occurred. A majority of the subjects first became aware of the change in sensation at approximately 100,000 cycles. Several subjects noticed it at about 150,000

Figure 4. Effect of frequency on perception current for hand holding number 8 copper wire

Figure 5. Effect of frequency on perception current with middle finger touching copper block

Figure 6. Effect of frequency on perception current with middle finger tapping copper block

cycles, and two subjects failed to observe any material change in sensation until a frequency of 200,000 cycles had been attained. Apparently the change in sensation is a definite change, rather than the gradual changes experienced at frequencies below 100,000 cycles. The sensation of heating at frequencies of 100,000 cycles also was reported by A. E. Kennelly and E. F. W. Alexanderson in their studies on this subject.[2]

The current required for perception at frequencies of 100,000 or more cycles was less dependent upon the rate of increase of the current than at frequencies between 30,000 and 90,000 cycles. A second phenomena was observed that indicates the difference in the nature of perception current in the higher frequency range. When currents of 100,000 or more cycles were adjusted to values slightly less than the perception values and maintained constant, perception was reported after an interval of several seconds. In contrast, for frequencies less than 100,000 cycles, currents of slightly less than the perception value were not perceived after an interval of several minutes.

These changes in perception phenomena with frequency also are apparent from the experimental data. It was observed in this investigation, and also in other investigations involving the response to electric stimulation[4,5,6], that regardless of the current required to initiate a given response, as long as the phenomena are similar, the deviation curves derived from the experimental data will have nearly identical slopes. It was noted that the deviation curves for the touching and tapping contact tests have the same slopes for a frequency range from 1,000 to 70,000 cycles. Similarly the holding contact deviation curves have the same slope for frequencies between 1,000 and 60,000 cycles. At very low frequencies the phenomena are more complicated as the muscles tend to follow the current alternations, and the deviation curves have different slopes. At the very high frequencies stimulation of the heat sensory mechanisms predominate, and again the slopes are different. The transition is completed between 100,000 and 200,000 cycles, and it would seem reasonable to expect that deviation curves for frequencies higher than 200,000 cycles might have slopes similar to those obtained for the 200,000 cycle tests.

Threshold of Perception on the Tongue

The current which can just be perceived with two contacts placed lightly on the tongue was determined using direct current and 60-cycle alternating current. The electrodes consisted of two number 18 wires, 1-inch long, separated by means of a bakelite separator. Platinum wire was used to reduce local galvanic effects. The electrodes were sterilized, washed with water, and dried between tests on different subjects. During the test, the subject held the electrodes lightly on the tip of his tongue and indicated when he first observed sensation as the current was gradually increased. There was considerable variation between successive tests on the same individual, and the average of several trials was taken as the perception value for the individual. The sensation might be described as one of taste, and is distinctly different from the characteristic tingling or warmth usually associated with

electric stimulation applied to other parts of the body.

The results using direct current for 115 men were: 44.7 microamperes mean; 16 microamperes median; 0.6 microampere minimum; and 783 microamperes maximum. Results for these men using 60-cycle alternating current were: 45.3 microamperes mean; 30 microamperes median; 4 microamperes minimum; and 315 microamperes maximum. The threshold of perception on the tongue is taken as the mean value and is approximately 45 microamperes for either direct current or 60-cycle alternating current.

It is apparent from these data, and also from a detailed statistical study, that the response did not follow a normal distribution but was skewed positively (toward the higher values). These findings are exceptional as the physiological response of a large group usually follows a normal distribution. A tentative explanation for the skewed response is that the small separation of the electrodes permitted the saliva on the surface of the tongue to shunt part of the current from penetrating to the nerve endings deeper in the tissues. Possibly the response might have more nearly approached a normal distribution had one electrode been placed on the tongue, with the circuit completed by an indifferent electrode located at some remote point, such as an electrode held in the hand.

Threshold of Perception on the Hand

Perception currents for 115 men with electrodes held lightly in the palms of the hands were determined using direct current and commercial 60-cycle alternating current. The results are given in Figures 1 and 2 respectively. The hands were moistened with a saturated salt water solution (NaCl) to reduce and minimize variations in contact resistances, and to permit the use of low voltages for safety. The subjects sat relaxed in a chair and rested the palm of each hand on smooth number 7 copper wires which were supported by the arms of the chair. The current was then gradually increased, and several trials were made to determine the smallest current that could be felt.

The results for 115 men using direct current were: 5.2 milliamperes mean; 5.0 milliamperes median; 2.1 milliamperes minimum; and 12.6 milliamperes maximum. The results using 60-cycle alternating currents were: 1.072 milliamperes mean; 1.05 milliamperes median; 0.44 milliampere minimum and 1.92 milliamperes maximum.

Figures 1 and 2 show that the response closely approximated a normal distribution. The mean and median values are substantially identical, and the mean value is considered to be the threshold. Therefore, the threshold of perception with electrodes held in the hand for direct current is taken as 5.2 milliamperes and 1.07 milliamperes for 60-cycle alternating current. The current likely not to be perceived is taken as the value corresponding to the one-half percentile. For direct current this is approximately 1.0 milliampere, and for 60-cycle alternating current 0.4 milliampere.

Deviation curves are helpful in analyzing the response to electric stimuli, and they were utilized in this investigation in a manner similar to that employed in previous papers in this field.[2,4,5] The solid dots of Figure 3 represent experimental points for the 60-cycle test with both hands holding the number 7 copper wire electrodes. The points are plotted in ascending order to show percentile rank as a function of the per cent deviation from 1.072 milliamperes, the mean of the group. The war period intervened between the completion of the 60-cycle test on the 115 men and similar tests recently completed on an entirely new group of 28 men.[6] Data for this new group are shown by the open dots of Figure 3. Since these data are plotted on probability paper, the straight line of best fit was drawn by eye through the 50th percentile and zero deviation point to establish the deviation curve.

In the latter tests, the 28 subjects grasped a polished number 8 copper wire electrode in the palm of the hand with light pressure and in a steadfast manner. The circuit was completed by an indifferent electrode which was clamped around the upper arm. The indifferent electrode consisted of a $1^1/_2$-inch wide lead strip wrapped with gauze. The strip was sufficiently long to nearly encircle the subject's upper arm, and the arm band was moistened with a saturated salt water solution to insure there being a good electrical contact.

To reduce the electric shock hazard, either the left or right but always the same hand and arm was used to prevent the current from passing across the body. It was found that there was less fatigue when the arm through which the current was passed was allowed to hang loosely at the side, rather than when the arm was allowed to rest upon a surface of a table or on the arm of a chair. For this reason the subject was instructed to let his arm hang free at his side during the tests. Preliminary investigation revealed no significant difference between the perception current obtained when the left or the right hand was used to hold the test electrode, however, the presence of minor cuts on a hand or fingers decreased the amount of current required for perception, and the choice of whether the left or right hand was used depended upon the condition of the skin. The threshold or mean value for this group was 1.067 milliamperes which compares favorably with the value obtained on the larger group eight years before.

The fact that a single line drawn on probability paper accurately represents the response for these two sets of data is significant because the data were obtained from different groups of subjects, at different times, and using different current pathways through the body. It is

200,000	Tapping	18	53.1	7	62.61

evident that the perception of electric current on the hands follows a normal distribution, and that results obtained from groups consisting of approximately 25 subjects are sufficient to permit valid conclusions. Furthermore, it is believed that a sufficient number was used to permit valid statistical predictions, not only for the particular group tested, but also for a normal cross section of the adult male population of the country. The probability of a given current being perceptible is arbitrary and the one-half percentile value was selected as a reasonable criterion for establishing the level of current not likely to be perceived. The current required for other probabilities may be obtained by using the following equation.

Milliamperes = (Mean of Group)(1 + Deviation from Mean corresponding to Percentile Rank Desired)

Perception current tests were made for three different contact conditions over a frequency range from 60 to 200,000 cycles. The contact conditions consisted of holding copper wires, resting the tip of the middle finger on a small copper plate, and tapping the middle finger on the copper plate.

The electrodes used for the holding tests consisted of $4^1/_2$ inch lengths of polished number 8 and number 4 copper wires. For the touching contact test, the tip of the middle finger was allowed to rest upon the copper plate without the exertion of pressure other than that caused by the weight of the finger. In the tapping contact test, the finger was raised from the plate, and then allowed to fall and make contact at a rate of one to two times a second. The test electrode for the touching and tapping tests consisted of a polished copper plate $2^1/_2$ inches by $1^1/_2$ inches by 3/16 inch, which was set on an insulated base and placed on a table in front of the subject.

Deviation curves similar to Figure 3 were established for the holding, touching, and tapping contact tests for the various frequencies. Space limitations prohibit inclusion of deviation curves for each frequency and contact condition. However, the per cent deviation for any percentile rank can be derived from the statistical data given in Table I. The $99^1/_2$-, 50-, and 1/2-percentile points obtained from these deviation curves were entered in Figures 4, 5, and 6, and smooth curves were drawn to show the effects of frequency on perception current for the three contact conditions. The middle curve, which is based on the means or the 50th percentile values, establishes the threshold of perception for the given conditions. The lower curve represents the current likely not to be perceived, while the $99^1/_2$ percentile curve is taken to define the upper limit of perception current.

For the holding contact tests only the most susceptible subjects were able to perceive currents of frequencies in excess of 60,000 cycles within equipment limitations. However, 19 of the group tested at 60,000 cycles reported perception at 70,000 cycles, and the mean value for the group was corrected according to the following equation

$$\text{Corrected Mean of Sample} = \frac{\text{Mean 60,000-cycle Perception Current for 25 Men}}{\text{Mean 60,000-cycle Perception Current for 19 Men}} \times \text{Mean 70,000-Cycle Perception Current for 19 Men}$$

The number of subjects reporting perception for frequencies in excess of 70,000 cycles was too small to justify statistical analysis; however, it is believed that the similarity of the shapes of the curves of Figures 4, 5, and 6 justify extrapolating the holding contact curves to 100,000 cycles. Since the nature of the sensation underwent a noticeable change beginning at about 100,000 cycles the extrapolation was not carried above this frequency.

Experimental results obtained from holding contact tests for the 28 men and four women are given in Table II. Although tests based on only four subjects are not sufficient to warrant more than passing comment, it is significant that the extreme values for the women generally fell within the range of currents perceived by the men. The differences in the mean values for men and women at any frequency are inconsequential.

A series of tests were made on ten male subjects using number 8 and number 4 copper wire electrodes held in the palm of the hand to investigate the effects of contact area. The results of these tests, which are given in Table III, fail to show a significant difference in the current required for perception as a function of electrode diameter. Although the ratio of surface areas of the two electrodes was 1.59, the amount of the surface of each electrode in actual contact with the skin may have been nearly the same due to the folding of the skin around the test electrode. The results reported by H. A. Carter and J. S. Coulter[7] indicate that the current required for perception increases as the contact area is increased, but not in direct proportion to the increase in area. An attempt was made to compare the current required for perception according to different physical characteristics. Inconclusive results were obtained when the subjects were grouped according to complexion and general build (heavy, medium, or slight); however, mean values of perception current for the men segregated into two age groups suggest that the current required for perception is somewhat dependent on age. The results of holding, touching, and tapping contact tests are given in Table IV. A greater number of subjects would be required to definitely establish the relationship between perception current and age.

Although the effects of wave shape were not investigated per se, it is believed that the factors controlling let-go currents[3,4] would also apply to perception currents. There is strong evidence to support the conclusion that the crest and not the rms value is the critical factor in stimulation with low frequency sine waves. The decrease in sensitivity with increasing frequency suggests that the effect of higher harmonics, or repetitive pulses superimposed on low-frequency alternating current, would have less and less effect as the frequency of the superimposed current was increased. Above 100 to 200 kc it might be expected that the sensation of heat would be largely masked out by the muscular stimulation of the lower frequency components.

Sufficient experimental data have been obtained to establish the current required for perception for several contact conditions over the frequency range from 60 to 200,000 cycles, and for direct current. The data follow a normal distribution, which permits valid statistical predictions to be made of the current not likely to be perceived, and that likely to cause perception.

The sensations observed as the frequency is increased fall into four frequency bands. The sensation produced by gradually increasing direct current is predominately one of warmth rather than of the muscular stimulation produced by low-frequency alternating currents. The sensations produced by alternating currents below approximately 10,000 cycles are characterized by a tingling or pricking sensation in the area adjacent to the point of contact, and at very low frequencies the muscles tend to follow the alternations of the current. A clearly defined threshold relatively independent of the rate of increase of current also is present in this range of frequencies. For frequencies between 10,000 and 100,000 cycles, the sensation produced by currents slightly above the perception level is less intense than that produced at the

lower frequencies; it is observed over larger areas around the point of contact, extending even into the wrist, and accommodation processes somewhat obscure the threshold boundary. An abrupt change in phenomena occurs between 100,000 and 200,000 cycles where the sensation becomes one of internal heating, and heating is the principal sensation produced by currents above 200,000 cycles.

The presence of many variables appears to exclude the possibility of any simple relationship between the current required to cause perception and frequency that would hold for the frequency range investigated.

Underground Hydroelectric Power Plants

PAUL E. GISIGER
NONMEMBER AIEE

Synopsis: In recent years a number of underground hydroelectric power stations have been built, mostly in Europe, and many others are under construction. While the last war has undoubtedly had some influence in making substantial protection of generating facilities seem desirable, it is pointed out that underground stations have been built long before the war, and that under certain circumstances there may be valid technical and economical reasons for the choice of this type of construction. Advantages that result from underground locations are discussed, and special emphasis is given to the points which need attention in the design, such as access and safety features, insulation, and ventilation. Several representative underground plants are described in some detail.

THE IDEA of putting hydroelectric power stations under ground is not a recent one. It is perhaps a sad commentary on our time that in any discussion of underground powerhouses in these days, the thought of protection against military attack is one of the main factors. The first sizable underground plant was built, however, at a time when the airplane was still in its infancy and its potentialities as a carrier of military destruction could hardly have been visioned. Progress, if such it be, in the art of carrying destruction to those installations upon which the industrial production of a country depends has now greatly promoted the interest in ways to make generating stations as invulnerable as possible. While under the circumstances this aspect cannot be disregarded, it still is important and interesting to consider the purely economical and technical factors involved. Under certain conditions these may indicate that an underground power house is the most desirable solution to be adopted, quite apart from any consideration of the war risk.

It will be necessary for our purpose to properly define an underground powerhouse. This is not as simple as it might seem. In most hydroelectric powerhouses, a considerable part or the whole installation is below adjacent ground levels. Sometimes turbines have been located in deep pits, connected by long vertical shafts to generators above ground, as for instance in the older Niagara plants. Plants of this type have sometimes been called underground plants. For the purpose of this paper, however, the term is limited to such plants in which the main piece of equipment, that is, the generator stands in a room which is completely submerged below the original natural ground level of the site.

It is fairly obvious that possibilities for the underground arrangement are more frequent for high-head than for low-head plants. Nevertheless, there exists also low-head underground plants. One of the most recent ones, the Lavey development on the Rhone River in Switzerland, has three 24,000-kw units driven by Kaplan wheels under 130 feet of head, see Figure 1.

While the turbine and the generator will of necessity have to be located underground, the transformers may be located

underground or above ground in a separate step-up substation. The first alternative is dependent upon the availability and dependability of high-tension cable and it is, therefore, to be found only in the more recent examples of this type. Among those are the Innertkirchen (1943) and Handeck II (1950) powerhouses in Switzerland (Figures 2 and 3), where power is taken from underground transformers to surface switchyards through 150-kv cables, and the Verbano powerhouse, to be completed 1952, where 220-kv cables will be used.

There also is an important interdependence between the general design and arrangement of a hydroelectric unit and the feasibility of its underground arrangement. It is obvious that with the underground arrangement, economy of space is highly important. Thereby the vertical shaft arrangement is favored, while among the older underground installations, whether they be equipped with Pelton or with Francis wheels, the horizontal shaft arrangement predominates. The more recent installations have, as a rule, vertical-shaft units. This is especially significant for Pelton wheel installations, such as the Innertkirchen, Figure 2, and Handeck II plants which provide recent examples of vertical-shaft single-runner Pelton units.

Advantages of Underground Location

The reasons for which hydroelectric stations have been put underground may be summarized as follows:

1. Under severe climatic conditions, such as in the far North (Porjus) or in the high Alps (Handeck II) construction operations can be continued all year round in an underground cavern, whereas above ground they might have to be interrupted for a considerable part of the year. Therefore, construction time can be saved.

2. The underground arrangement often allows more liberty in the choice of location of the powerhouse. In the high Alps the necessity of keeping away from avalanche paths is avoided; in steep, narrow river canyons there may be no space for a conventional powerhouse and appurtenant works at the point which is indicated by the longitudinal river profile as the most desirable powerhouse location. The length of expensive pressure tunnels may be shortened by providing instead a longer, but less expensive, free-level tailrace tunnel with the location of the powerhouse away from the river inside the mountain. This results in the additional advantage of replacing relatively flat-sloped steel penstocks with a steep or even vertical pressure pit which usually is considerably cheaper. The shorter pressure tunnels and penstocks will furthermore facilitate the speed regulation of the turbines.

3. With an underground location, foundation difficulties which are often present in alluvial river bottoms are completely avoided and the foundations themselves are often less voluminous and, therefore, cheaper than with the conventional type.

Construction Features

The general arrangement of a hydroelectric powerhouse is based on the function and interrelation of its main items of equipment, whether the powerhouse is above or below ground. Plans and cross sections of underground powerhouses follow, in general, the same lines as those of the conventional type. There is perhaps a little more emphasis on economy of space, because the incremental cost of additional space increases more than with the outside type. It is surprising, therefore, that in none of the European underground installations with vertical-shaft units the arrangement with thrust bearing below the generator, which has become so common in America, has been used.

It is axiomatic that the location for a powerhouse cavern should lie in perfectly sound rock because constructive measures to counteract the effect of pressure zones in unstable rock, such as are sometimes unavoidable in railroad or power tunnels, would hardly be economically feasible in case of a powerhouse. A thorough geological investigation is, therefore, still more indispensable in case of a proposed underground powerhouse than for other features of a hydroelectric project.

Construction of the cavern itself is beyond the scope of this paper. It may be mentioned, however, that for Swiss conditions it has proved advantageous to start excavation from several places at once. A good procedure is to drive four headings along the four corners of the cross section. The rock between the two upper headings is then removed, so that the top part of the cross section, between the springing lines of the roof arch, is excavated. It is then possible to concrete the roof arch, using the rock still in place immediately below as a working platform; the headings at the top and bottom of each side wall are connected with a vertical slot, the main rock prism removed, and at the same time the facing of the side walls is placed, see Figures 4 and 5.

Sometimes there is more than one cavern to excavate. In case of the Innertkirchen and Handeck II powerhouses which work under heads of 2,050 and 1,450 feet respectively, there is a valve chamber on the upstream side of the powerhouse proper, see Figure 6. This is a safety measure against flooding of the powerhouse by the possible failure of a valve. The valve chamber is normally closed off against the powerhouse with a heavy bulkhead door and provided with a discharge canal to the [illegible]

As may be seen from Figures 1, 2, and 7 the inside walls and ceilings of all recent underground powerhouses are not in direct contact with the rock. In some cases, the walls are lined with concrete with a thin false wall set in front of the lining; in others, the rock remains unlined, with an independent wall placed in front of the rock. In either case, the resulting air space not only insures against any seepage water getting into the actual building, but is useful as an airduct. The roof is always a solid concrete arch to insure against possible cracking off of any rock particles. Below this arch there is usually a light false ceiling. The space above the false ceiling is again useful for insulation as well as ventilation.

Figure 8. General arrangement of Brommat development

As a matter of curiosity, the Cotilia Powerhouse of the Terni Company in Italy may be mentioned. This has all the characteristics of an underground powerhouse, but has actually been built in an open pit, and covered with a fill about 50 feet high. It nevertheless also is provided with a somewhat modified form of double-wall and ceiling construction.

In Table I are listed some of the more notable recent underground power plants.

Power Take-Off

It is evident that power has to be taken away from an underground powerhouse through cables to an outside starting point for an overhead line. In this respect the underground installations can be clearly divided into two classes: Stations where transformers are located above ground away from the powerhouse, so that the power is carried outside at generator voltage, and stations with transformers located in the powerhouse cavern itself, in which case the power has to be carried outside in high-tension cables. In older plants the outside transformer station was the rule, but now there is a definite trend to have transformers located next to the generators. As soon as vulnerability in war is a consideration, then it is desirable to give the transformers the same degree of protection as the generating equipment. The experience of the last war points to the fact that shell or bomb damage to switching installations is relatively easy to repair, whereas a hit on a transformer may seriously cripple a transmission system.

A low-tension cable installation between an underground powerhouse and an outside step-up and switching station has no different problems than those present at any normal powerhouse with transformers located not directly adjacent to the generators. The cable tunnel is usually combined with the access tunnel, although separate tunnels for outgoing cables also have been used. This holds for high-tension as well as for low-tension cable tunnels. An example for an outside transformer arrangement is the Brommat station in France, built in 1932, Figure 8, where power goes out at the generator voltage of 15,000 volts to a transformer and switchyard. The control room, as well as shops and offices, are located in a service building at this switchyard.

An example for the transformers located alongside the generators is the Innertkirchen plant in Switzerland, completed in 1943, where current is stepped up to 150 kv and then taken to an outside switchyard with high-tension cables located in a tunnel, see Figure 2. The same scheme has been followed for the Handeck II Station, immediately upstream from Innertkirchen, which is under construction and will go into service in the near future. In the Lavey Station on the Rhone River, which has been under construction during the same period, the transformers are located in an outside step-up and switching station.

Ventilation and Lighting

The necessity of providing large tunnels for the access of people and equipment as well as the exit of power and control cables, Figure 9, makes it relatively easy to have an ample turnover of air in an underground powerhouse. The false walls and ceilings which are usually provided to insure dryness of the vital spaces lend themselves to be used as airducts and leave the designer a considerable amount of freedom in arranging for an advantageous circulation of fresh air, and the exhaust of used air. As a rule, fresh air is taken in through the main entrance or cable tunnel and returned through special exhaust ducts located in or near the ceiling. The fans to push or pull the air through may be located at the most convenient point in the circuit. In most of the recent underground installations the generators are cooled with a closed system and, therefore, the amount of heat to be removed is moderate. Depending on climate and season, it may be possible that for considerable periods of time natural ventilation is sufficient and fans do not have to be operated.

With any scheme of ventilation it is essential that there are no rooms or places which are bypassed by the general flow of air. This is especially important for the control room. In most cases it has been found necessary to insure proper working conditions in the control room through a secondary system of ventilation which either pushes fresh air through or exhausts used air from the control room. In a number of instances it has been found satisfactory to introduce the fresh air at the top, and exhaust it near the bottom of the control room because the warm air coming from heat-producing instruments is removed before it has spread out over large parts of the room.

In some underground stations the power is carried outside on open bus bars. In such cases it is preferable to use the bus tunnels for the exhaust rather than for the admission of air, on account of the heat released by the bars.

As might be expected, it has been the general experience that temperatures inside an underground station follow the daily and seasonal variations of the outside temperature only with a greatly reduced amplitude. As a general rule, it appears that working conditions in such a station are in no way inferior to those above ground.

While the lighting of an underground station offers no new problems, it is obvious that for practical as well as psychological reasons it should be given very careful consideration. The advances made in recent years in methods of indirect lighting and the use of fluorescent lamps can be applied to great advantage in a place where daylight is absent 100 per cent of the time. Attention is called to Figures 3 and 10, which show the lighting arrangements in the Innertkirchen and Handeck II Stations.

Some Individual Developments

Porjus Development, Sweden

This development is mentioned briefly because it is the forerunner of all other underground plants. Its construction was begun in 1910 and the initial installation

completed in 1914. It is located north of the arctic circle on the Lulea River. The underground location was indicated by topographic and still more by climatic reasons. The total head of the plant is 183 feet; its general arrangement with individual vertical penstocks recalls somewhat that of the earlier Niagara plants and conveys the thought that the latter could have become underground plants by a relatively small modification. The most significant difference of Porjus against more recent plants is the arrangement whereby the turbines of its horizontal-shaft units are recessed into separate compartments in the rock, while the generators only are located in the continuous, common generator room. Transformers, as well as control room, are located above ground.

Brommat Development, France

This plant, in operation since 1932, has all the features of the modern underground plant. It is located on the Truyere River which originates in the highlands of central France and discharges through the Lot River into the Garonne River. With a static head of 855 feet and a plant discharge of 2,960 cubic feet per second it has a total capacity of 186,000 kw in six units. The reason for locating it underground was lack of space in the narrow river gorge. Water is brought from the Sarrans upstream development through an equalizing basin and then through a pressure tunnel which near its end splits into two conduits leading into separate surge chambers. From each surge chamber a vertical penstock or pressure pit drops to the power house, dividing itself at the bottom into three branches corresponding to the three units fed by each penstock, Figure 8. The steel lining of the penstocks varies in thickness from 1/2 inch to $1^3/_4$ inch, backed up by 12 inches of concrete between steel and rock. Powerhouse as well as pressure tunnels and penstocks are located in compact granite rock.

The powerhouse shown in Figure 7 is equipped with vertical-shaft Francis turbines. Ahead of each spiral casing there is a spherical valve with the usual by-pass and control features. Special precautions were taken against the risk of failure of the cast-steel turbine or valve casings; the quick closing gates at the head of the penstocks are controlled from the powerhouse, any water entering the turbine floor can freely discharge into the tailrace, and the three stairwells between the turbine floor and generator floor can be closed with emergency bulkheads.

The generators are equipped with water coolers for closed-circuit ventilation.

Fresh air for the powerhouse is admitted through a special air tunnel more than 3,000 feet long paralleling the tailrace. A distribution tunnel at draft tube elevation "F" in Figure 7, distributes the fresh air through the length of the powerhouse; it then moves up through the space between rock and side walls into the various powerhouse rooms and is finally evacuated above the false ceiling into the lower section of the inclined access tunnel. A fan at the outside end of this tunnel keeps the air moving.

Access to the powerhouse is provided through an inclined tunnel, Figure 8, 18 feet wide and starting at an outside building in which are located the control room as well as shops, offices, and so forth. This tunnel is equipped with a cable car on a wide gauge track for the transport of heavy as well as light equipment and personnel; along its side walls all control cables are carried from the powerhouse to the control room. Immediately below this tunnel, separated from it only through a concrete slab, is the tunnel for the 15-kv generator cables. This tunnel ends in a low-tension bus room. Step-up transformers are located above this room in the open. The tailrace is again formed by a tunnel in solid rock of more than 3,000 feet length. At its beginning, where the six draft tube discharges are joined together, is a surge chamber to insure uniform free flow.

Innertkirchen Powerhouse, Switzerland

The Innertkirchen Powerhouse is the second step of the Grimsel development on the headwaters of the Aare River. The main feature of this development is a large storage reservoir at an elevation of 6,260 feet at the end of the glaciers on the west flank of the Finsteraarhorn, the highest peak in the Bernese Alps. From this storage reservoir the water goes through Handeck I Powerhouse, completed in 1932, which utilizes a head of 1,790 feet and is of the conventional type. From the discharge of this plant the water is taken through another pressure tunnel and penstock to the Innertkirchen Powerhouse, utilizing a head of 2,200 feet. This second powerhouse was completed in 1942 and is of the underground type. Its construction was decided upon in 1939 and the political situation at the time was making bomb-proof construction desirable; but the underground arrangement had actually been considered several years earlier on account of the economies to be obtained from the embedment of the penstock and its manifold into solid rock, and for safety against rock slides which were a risk at that location.

The pressure tunnel from the upper

Figure 9 (left). Entrance to Innertkirchen powerhouse

Figure 10 (right). Interior of Innertkirchen powerhouse

Figure 11. View of Innertkirchen Valley

plant to the Innertkirchen surge chamber is 32,700 feet long and dimensioned for a flow of 920 cubic feet per second. From the surge chamber a single inclined pressure pit leads to a manifold where the feeders to the five units branch off, Figures 6 and 11. The pressure pit varies in diameter from 8.54 to 7.88 feet, its steel lining in thickness from 1/2 inch to 13/16 inch.

Pressure pit and powerhouse are located in hard crystalline schist.

From the general plan of the powerhouse, Figure 6, it will be noted that between the branching-off point of the unit feeders and the powerhouse there is located a separate valve room where each conduit can be closed off by spherical service and emergency valves. The special valve room insures against flooding of the powerhouse by failure of a valve casing.

The powerhouse cavity has a minimum vertical rock cover of 130 feet, but the valley flank is so steep that the length of the horizontal access tunnel at generator floor level is only about 130 feet.

The concrete arch above the generator room is not reinforced, but care was taken to fill out all crevices between it and the rock as well as in the rock itself by pressure grouting. The false ceiling underneath is built up of corrugated Transite, Figure 2.

The 42,000-kw units are of the vertical-shaft type with 2-nozzle Pelton wheels, Figures 2 and 10. An innovation is the support of the generator directly on the steel casing of the turbine without an intermediate structural floor. Thereby the foundations were simplified and access to turbine and generator made easier.

Each generating unit is directly connected to a 13/150-kv transformer located in the powerhouse adjacent to generators. From the transformers the current is taken through 150-kv cables in a special cable tunnel to an outside substation.

The powerhouse is reached through a short access tunnel, Figure 9. A 1-meter gauge siding connecting to the railroad line serving the upper Aare Valley enters through this tunnel. Directly underneath is a smaller tunnel for control cables and fresh air. Air is pushed in through a fan at the entrance, flows through the powerhouse upwards into the space above the false ceiling and is exhausted again through one exit tunnel at each end of the cavity. The alignment of the tailrace tunnel could be so chosen that its entire length of 4,240 feet is in solid rock.

The Handeck II Powerhouse, Switzerland

The Handeck II Powerhouse forms a further extension of the Grimsel development and is now under construction. It utilizes water from drainage areas not contributing to the Handeck I Powerhouse and its discharge will increase the flow through the Innertkirchen plant. The Handeck II Powerhouse will contain four 24,000-kw units under 1,450 feet of head and will, in most respects, be similar to the Innertkirchen Powerhouse, see Figures 3, 4, and 5. It will go into operation in 1950.

Lavey Development

This development, belonging to the city of Lausanne and located on the Rhone River, is an example of an underground powerhouse for a low-head installation. Its head of 150 feet is created by cutting off a bend in the river with a pressure tunnel of large dimensions for a plant discharge of 7,000 cubic feet per second. The plant is equipped with three Kaplan units of 24,000 kw each, Figure 1. In its general arrangement the powerhouse is not much different from the preceding ones, except for differences resulting from the different type of turbines and from the outside location of the transformers. This plant also will go into operation in 1950.

Other Underground Developments Under Construction

Underground powerhouses have almost become the rule rather than the exception for new developments in many sections of Europe. A considerable number of them now are under construction. It would be impossible to name all of them. Among the more notable plants may be cited the Harspranget Plant in Sweden, just completed or about to be completed, with an installation of 285,000 kw; the Kilforsen Plant, 240,000 kw, also in Sweden, to be completed in 1954; the Santa Massenza and Provvidenza plants in Italy with installations of 284,000 and 150,000 kw respectively and the Verbano Plant in Switzerland, about to be started, for an installation of 100,000 kw.

No Discussion

Centralized Control Desirable for Single Boiler-Turbine-Generator Units

J. A. LIND
NONMEMBER AIEE

J. M. GEIGER
MEMBER AIEE

CENTRALIZED control of steam-electric generating units has been a natural and gradual evolution over the years. It has been accelerated by such factors as development of suitable equipment and controls, creation of new plant heat cycles, and rapid growth in the size of the units and of the electrical utility industry. The authors believe that current controversies over centralization of controls are concerned primarily with what shall be included and how centralization is to be accomplished, and not so much with the basic idea of centralization.

In generating stations as well as over-all power systems, the electrical engineers have been able to progress further than the mechanical engineers in this matter of centralization of controls. It is not unusual for power systems with generating plants spread over hundreds of miles to have centralized, and even automatic, control of machine loading from a central load-dispatching and frequency-control station. The purpose of such controls is to co-ordinate the loading of the controlling machines as well as to distribute load among them as required by system conditions. On the Niagara Hudson System, installation of such equipment has resulted in much better control together with less load swing on the machines under control. Previously some of the swings consisted of unnecessary transfer of load among generating stations as a result of unco-ordinated manual control.

Within a single generating station, certain operations need to be co-ordinated with each other. An early problem was the co-ordination of firing in battery many boilers serving a group of turbine generators. With that arrangement, the boilers installed for a particular turbine could serve any other turbine. So long as steam pressure was maintained, it did not especially matter how load was transferred between generating units. With boiler sizes then employed, many more boilers than turbines were required. Control schemes employing large master-pilot steam gauges, steam pressure regulators, and eventually complete combustion control systems seemed to solve a large part of the boiler-room problem. The boiler personnel required constituted a department in itself and it seemed best to let it operate as such. At the same time, the electrical operators were concerned with matters in addition to the generators. They supervised local feeders, tie lines, street lighting, and so forth. Consequently, an over-all plant control scheme developed whereby the electrical group became divorced from the mechanical group and the mechanical group further divided into a turbine-room group and a boiler-room group. This division of responsibility contributed to poor co-operation because of lack of understanding of each others' problems. These conditions laid the groundwork for improvement.

It had become the practice to load machines at a prescribed rate which had been determined by boiler flexibility. It was learned that this rate was not a fixed thing so that sometimes the full capability was not realized and at other times the boiler room was overtaxed. Addition of a steam-header pressure gauge in the electrical control room permitted taking load swings at such rate as the boiler room could stand them at that moment without lowering steam pressure to the point of jeopardizing capacity of steam-driven auxiliaries. Addition of a station load megawatt meter in the boiler room also permitted the boiler operators to do a better job by knowing the magnitude and rate of demands being placed on them. Further co-ordination was attained by use of intercommunication facilities.

When Oswego Steam Station was being designed in the late 1930's a unit system was decided upon, a unit consisting of a boiler, turbine, and generator. No steam, feedwater, or electrical interconnections at generator voltage were provided between units. Merits of the unit system in this case have been described elsewhere.[1] The controls for such a station required an entirely new approach and presented an opportunity for major improvement.

Let us consider such a station with two or more units with no mechanical or electrical interconnections except the transmission system. Suppose now that station load is to be changed. Either unit may assume the whole change or both may share it. On the other hand, suppose the total station output is to remain constant but reapportioned between units. Without steam interconnections, both boilers are subjected to the conditions which accompany a station load change. As the load on one unit is changed, all of the pump outputs must be changed and the firing rate of that unit's boiler must be changed, requiring change in output of pulverizers, feeders, and feedwater regulators. Some of these functions may be automatic and some, such as starting of additional fans and pumps, may be manual. It is valuable, therefore, that the several operators know the magnitude and speed of load change on the unit they are handling as quickly as possible. There are three ways of speeding up this intelligence:

1. Duplicate instrumentation at the several operators' locations.
2. Use a public address system.

Paper 50-187, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted November 17, 1949; made available for printing May 8, 1950.

CONTROL ROOM

Figure 1. Arrangement of main operating floor for units 1 and 2 at Oswego steam station showing convenient central location of control room

A similar control center has been provided for unit 3 and future unit 4 which is under construction. Control panel arrangement is shown in enlarged plan of control room

3. Locate all affected operations at one point.

The decision as to which to employ depends on various factors such as:

1. Cost.
2. Suitability and conformity as an extension to an existing station.
3. Allowable time to make necessary changes.
4. Division of responsibility between operators.
5. Expediency.

Studies of loadings for the Oswego Steam Station indicated that it would be largely a bulk power producer. Also, there would be periods of minimum load, stand-by service during heavy run-off to the system's hydro stations, and periods during which it would be regulating. It would be firmly tied into the 115-kv transmission system and there would be few local feeders. These conditions required that each unit be capable of operating over a wide load range and that flexibility of control be provided to meet the variable demands of the system.

A conception, believed to be original, was that of a straight-line organization for each unit, originating with a unit operator who would be in a position to supervise all operations of one boiler-turbine-generator unit. Normally he would control input to suit output, but he also would control output to not exceed the capability of the unit and its associated equipment. In working out details of such a system, including arrangement, cost, and personnel, it appeared more feasible to apply the scheme on a 2-unit basis.

A central control room was located in the building bay between units, and in it were installed an electric switchboard for the two generators, their exciters and related auxiliaries, and a mechanical control board for each of the boiler-turbine units and their auxiliaries. Figure 1 shows the arrangement of the panels in the control room and the orientation of major equipment on the main operating floor. Glass areas in the control room walls permit observation of activities in parts of the boiler room and turbine room. A mirror near a furnace door is used to observe that furnace lighters and burners ignite properly. Other mirror systems afford a view of the bicolor gauge glasses.

Figure 2 shows the control room with the electric control board in the distant center and the two mechanical control boards on the sides. The electric board contains the usual switchboard controls and meters and the mechanical control board contains those instruments, meters, gauges and controls usually found on the boiler-control panel and turbine-control panel. The small size of these main control panels has been accomplished by bringing only essential controls and instruments to this location. Liberal use of telemetering has permitted using smaller instruments on the panels. To illustrate: at each boiler feed pump there is a local panel with flow meter, pressure, gauges push buttons for auxiliary oil pump, recirculation control relays, thermometers, and so forth; in the control room there are only an ammeter, control switch, air control subpanel, and a telemetered flow indicator in a multiple draft gauge type of instrument.

The control room is air-conditioned for the comfort of the operators, and has been arranged for their convenience. They can communicate with the auxiliary operators either by telephone or public address system. Many abnormal operating conditions are called to their attention by an annunciator. Principal auxiliaries of the main units are under their direct control. For the most part this equipment is stopped and started manually, but automatic speed and throttling control is provided. So far as possible, related instruments and controls have been grouped together.

Starting from the boiler-room end, the mechanical panel has a section for soot blowers, then a section for pulverizer and burner controls, followed by the steam pressure and combustion control, including control switches for draft fans. Controls for the turbine and its auxiliaries are at the turbine-room end of the panel. Control of condensate from the condenser to the boiler is located on a section of the panel between the boiler controls and the turbine controls.

The central section of the electric switchboard contains frequency and tie-line loading controls. On either side of center there is a section for instruments and controls associated with one unit, followed by panel sections for auxiliary power boards. Towards the ends are panel sections for local feeders. Station watt-hour meters are on the end wings of the panel.

It was evident that some operating department functions would be on a plant basis rather than a unit basis because they did not immediately affect ability of any one unit to control load. Divorcing these functions from the unit operators simplified the centralization of controls considerably. Some of these functions were:

1. Cool handling to the bunkers of each unit.
2. Slag removal from the boiler ash hoppers.
3. Fly ash removal from the dust collector hoppers.
4. Supervising circulating water screens and gates.
5. Station water and compressed air services.

Most of the functions described were provided with failure or trouble alarms and some of the critical ones were called to the attention of the unit operators.

It seemed unimportant that the unit operators have control of functions related principally to start-up, hence remote control of these items was provided only when convenient. Such items included steam jet air ejectors and sealing water to the turbine. It should be noted that while ejectors may be added or removed from service during operation, they require no adjustment because of machine load changes. The evaporator plant was not placed in the centralized group because the immediate demands of the unit are supplied from condensate storage tanks, and therefore the evaporators need not be co-ordinated with operation of the main units. Control of automatic soot blowers might also have been omitted from centralization, but it was convenient to include them, and since they may operate up to 80 per cent of the time, there is some value in having their program control under surveillance of the operators.[3]

Our purpose, then, has been to centralize control of all those functions which require adjustment for safe and dependable operation over the normal load range of each machine which, in the case of Oswego, represents a load range from about 10 to 100 megawatts. The inclusion of safe operation necessitated provision for emergency shutdown.

There has been advocacy of separation of electric controls,[9] that is, the electric switchboard from the boiler and turbine controls. The authors have no disagreement with such separation in some instances. It is conceivable that some plants, located in load centers, may require more space and personnel in connection with transmission and distribution than in connection with the electric control of the generating units. In such instances, we suggest that consideration be given to separating the extraneous jobs from the power plant jobs instead of separating the power plant jobs. If sufficient extraneous electric controls are to be located in the power plant, a separate control location might well be established for them.

The value of closely co-ordinated operation of a unit by means of centralized control is illustrated in nearly every operating abnormality.

For example, when there is an alarm of coal failure to a mill, the electrical operator is immediately alerted and stands by to keep steam pressure up. This results in load drops of 5 or 10 megawatts for a few minutes on two or three days a month during wet and frozen coal periods. Probably the load drops would be greater due to efficiency loss if steam pressure were allowed to fall off.

When operating on block loads, and the load supervisor calls for a change, the switchboard operator announces what is to be done as he steps to the panel. The mechanical man will advise him if there is reason to make the change in any manner different from normal. If a quick change is required, the rate of change is determined by ability to maintain water level, steam pressure, draft or whatever may be most critical at that moment. If electrical trouble occurs, the boiler operator likewise knows at once the nature of changes necessary to restore order. The two operators watch each others' moves and to some extent observe each others' instruments.

A new station, identical to Oswego in arrangement, is now under construction, and similar centralized control will be incorporated. The supervising operators, who will come from a plant in which there is a separate electrical control room, are enthusiastic about the single control room arrangement for the new station. They plan to give all of the control room operators the type of training required for unit operators so that any one of them can handle either the switchboard or mechanical control boards. This will simplify the setting up of shift schedules by not having two types (electrical and mechanical) of control room operators, and it also will permit maximum flexibility of manpower in times of trouble. That is, each of the operators who has no trouble on his board can assist any other one.

The units comprising the initial installation will be of the reheat type. Study of the operation of such units indicates a greater need for co-ordination between boiler, turbine, and generator controls than is the case with straight-through machines. A joint recommendation of the boiler and turbine manufacturers calls for automatic trip-out of fires in the event of trip-out of the generator or sudden major load loss. It also calls for some of the meters and supervisory devices to be available to both the mechanical and electrical operators. Centralization of controls is an ideal way of doing this.

In conclusion, then, the desirability of

Figure 2. Control panels for units 1 and 2 at Oswego Steam Station

Electric control panel is in background and each of the two panels on the sides contains the instruments and controls for one boiler-turbine unit and its auxiliaries

centralized controls in generating stations of the independent-unit type of design has been confirmed by nearly ten years of experience with two units at Oswego. Observations at Oswego and independent studies have demonstrated its advantages to a different operating group which is experienced with separate electrical control rooms. Even greater benefits can be foreseen when centralization is applied to the new, more complicated heat cycles.

The Determination and Allocation of the Capacity Benefits Resulting from Interconnecting Two or More Generating Systems

C. W. WATCHORN
MEMBER AIEE

THE interconnection of two or more electric generating systems always reduces the amount of generating capacity required to be installed as compared with that which would be required without the interconnection. The amount of such reduction may be large or small, depending on the interrelation of the various factors and characteristics of the interconnecting systems and the desired level of service reliability. The installation of the transmission facilities that are necessary to bring about the interconnection may or may not be justified. This fact can be determined only by a proper economic comparison of the alternate installations.

Having once decided on interconnecting two or more generating systems, some plan or basis is necessary for the allocation of the resulting capacity benefit among the interconnecting systems.

This paper treats generally of the several considerations and factors involved in the determination of the capacity benefit resulting from interconnecting several generating systems as one factor in the determination of the justification of the interconnection, and also as a basis for determining the installed capacity obligations of the interconnecting systems. In addition, the article submits what is believed to be a logical and equitable basis for the determination of such obligations as the result of the allocation of such benefit among the interconnecting systems.

Paper 50-188, recommended by the AIEE Joint Subcommittee on Application of Probability Methods to Power-System Problems and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950. Manuscript submitted July 5, 1949; made available for printing May 1, 1950.

Determination of Capacity Benefits

The determination of the capacity benefits resulting from the interconnection of generating systems involves only the evaluation of the composite effect of all the diversities that may exist among them. These diversities, in addition to those resulting from any differences that may exist in the times of occurrence of daily peak loads, include those properly involved in "long-time load-forecasting errors," those resulting from the amount of variation in the magnitude of the daily peak loads, from maintenance requirements, seasonal reductions in the load-carrying capability of both the hydro and steam capacity and from forced outages of generating facilities, including the effect of the number, sizes, pressures, and arrangements of the turbines and boilers. The true composite effect of all these diversities can best and most logically be evaluated by means of probability methods, since such methods automatically give proper weight to each of these factors in accordance with the various conditions relating to the several systems. Various phases of the application of probability methods to this type of problem are discussed in several papers that have been presented during the past several years.[1–6]

Figure 1 illustrates certain of the general results obtained by an application of probability methods to the problem of determining the capacity benefit resulting from the interconnection of two systems. This illustration is developed with respect to Systems B and C treated in the Tables. The curve for the two systems combined, as well as those for the systems separately, are shown on the basis that there are no intra- nor inter-system transmission limitations. If two or more generating systems interconnect, assuming no transmission limitations, they operate, with some given amount of installed generating capacity, at the same level of service reliability regardless of what their separate ideas or desires may be. Thus, when two or more generating systems interconnect, the capacity benefits of the interconnection must be determined on the basis of a mutually agreeable level of service reliability.[7] In other words, regardless of any differences in the reliability that may have existed among the several systems for separate operation, some agreement must be reached as to the capacity requirements of the several systems predicated on a degree of reliability that will be the objective with interconnected operation.

It is believed that a reasonable level of service reliability, when the effect of probable load forecasting errors is included in the evaluation, is a probability of failure to carry the load of in the order of an average rate of one day in from eight to ten years. For the purpose of this illustration, a probability of failure to carry the load one-half the distance between probabilities of 0.001 and 0.0001 was used, which corresponds to the probability of failure to carry the load at the average rate of one day in 8.66 years. The computed capacity benefit resulting from interconnecting Systems B and C, or the reduction in the installed capacity requirements for this degree of reliability, is 170,000 kw with adequate interconnection capacity, which is the difference, along the dotted horizontal line, between the two solid line curves to the right of

Figure 1. Probability of failure to carry the load versus installed capacity

Figure 1. This is the basic or the indicated maximum capacity benefit, and results when the transmission capacity is equal to at least one-half the amount of such computed deferrable capacity. With interconnecting transmission capacity smaller than one-half the amount of such computed deferrable capacity, the indicated capacity benefit would be reduced to an amount equal to twice that of such smaller transmission capacity.

These results are modified by the fact that the units are of discrete sizes. Because of this fact it would be a remote coincidence if just exactly the desired level of service reliability were obtained. Although a slightly smaller level of service reliability than that selected as standard may be tolerated, what may otherwise appear to be a comparatively small capacity deficiency may result in a grossly inadequate degree of service reliability. This characteristic is indicated by the steepness of the curves in Figure 1. Consequently, as a practical matter the experience probably will be that a greater amount of installed capacity generally will be available than that indicated as being the minimum requirement. This experience would be the case regardless of whether or not the systems are interconnected. The result is that when two or more generating systems are interconnected, additional benefits over those computed in the manner illustrated by Figure 1 are obtainable as the result of staggering the installation of capacity among the interconnecting systems. The amounts of such additional capacity benefits are variable and depend on the differences between the indicated and actual installed capacity requirements, the capacity of the individual units being installed, and the amount of the transmission capacity.

Figure 2 shows the average capacity benefits, over a period of years, resulting from interconnecting Systems B and C with various interconnecting transmission capacities and various capacities of the individual units being installed. The manner in which these results were determined are given in the Appendix.

It will be noted that the curves of Figure 2 are discontinuous for transmission capacity equal to half the capacity of the units being installed, half the capacity benefit computed in the manner illustrated by Figure 1, and transmission capacities equal to the sum of these two latter amounts. The reasons for these characteristics are seen from the Appendix and Figure 4 treated therein. These charac-

Figure 2. Interconnection capacity benefits versus transmission capacity (Systems B and C)

teristics mean that the incremental capacity benefit resulting from the interconnection decreases as the interconnecting transmission capacity increases. This relationship is shown in Figure 3.

Note the converging characteristic of the two curves to the right of Figure 1, as the service reliability decreases or as the capacity becomes tight. The reason for this characteristic is that interconnections do not create capacity. They rather only make possible greater effective use of the available generating capacity, which use decreases quite rapidly as the load, as related to some specified amount of installed generating capacity, increases and the amount of the installed generating capacity in excess of the load decreases. This is particularly true when the interconnecting facilities are substantial and are not the limitation. By contrast, there is no comparable decrease in the effectiveness with which the alternate capacity may be used as the capacity becomes tight. Thus, for a low level of service reliability, the capacity benefit of an interconnection is greatly reduced. Additional generating facilities are then obviously required to restore a reasonable level of reliability, but such additional generating capacity would be smaller with an interconnection than without. Thus, an interconnection is a substitute for installed generating capacity only where properly backed up. It is believed that a corollary to this characteristic is that the generating capacity always should be installed rather than the alternate transmission facilities, unless the economic comparison shows that the interconnection is clearly justified by an attractive margin.

Allocation of Capacity Benefits

When it is concluded that the interconnection is to be made, one of the questions to be decided is that of the allocation of the resulting capacity benefit among the several participating systems. Several possible bases for allocating such benefits readily come to mind, for example:

1. The benefit should be divided equally among the participating systems.

2. The installed capacity requirements of each of the participating systems should be proportional to that of each for separate operation.

3. The reserve requirements of each should be proportional to that of each for separate operation.

4. The reserve requirements of each should be proportional to the installed capacity requirements of each for separate operation.

5. The reserve requirements of each should be proportional to the peak load of each for separate operation.

6. The benefit should be divided among the participating systems in proportion to the additional benefits obtained as the result of treating each participating system as a newcomer in the interconnected group, which method may be termed "the additional benefits method of allocation."

7. The benefit should be divided among the participating systems in proportion to the benefits for all combinations of two's among them, which may be termed "the mutual benefits method of allocation."

There may be still other bases.

When only two systems participate in an interconnection, the capacity benefit is a mutual benefit to which neither system by itself contributes any more nor less than the other, the benefit thus being impossible of attainment without the other system, with neither the size, nor any other characteristic of one system by itself, contributing anything whatsoever to the ultimate capacity benefit. These facts lead to the conclusion that when only two systems are involved in an interconnection, the resulting capacity benefit should be divided equally between them. The application of suggested methods 1, 6, and 7 all give this desired result for a 2-system interconnection. It would only be under unusual circumstances that suggested methods 2, 3, 4, and 5 would give this same result. It would be a very unusual coincidence that the capacity benefit would be divided equally under these latter suggested methods unless the systems were exactly equal in size and otherwise similar in essential characteristics. When more than two systems are involved it would appear that a logical and equitable requisite would be that the benefit allocated to any one of the participating systems should not be reduced by the addition of any one or more of the other participants into the interconnection. Suggested method 1 generally will not meet this requirement because, if the result with the inclusion of certain of the participating systems in the interconnected group is that small, additional capacity benefits are obtained for all combinations with the other participating systems, while with the similar in-

A, B, and C	5,395	4,785	5,645	250	610

clusion of other participating systems the additional capacity benefits are large, and the total benefit were allocated equally among all, those systems for which the additional capacity benefits are large would be allocated a smaller amount of capacity benefit when those systems for which the additional capacity benefits are small are included than when such latter systems are not included. Such a result is inequitable to those systems for which the additional capacity benefits are large, and they would have a just basis for objecting to further interconnection that would increase their capacity requirements, even though the making of such interconnection would be justified from an over-all point of view. A somewhat opposite result would be obtained by the use of suggested method 6, "the additional benefits method of allocation," in that, if relatively larger additional benefits are obtained as the result of the inclusion of certain of the participating systems for all combinations with other systems, than with the inclusion of the other systems as additional participants such system would be allocated such a large portion of the total capacity benefit under this method that cases may well result for which other participating systems would be allocated a smaller amount of capacity benefit when such system is included in the interconnection than when it is not included.

These considerations then leave us with only suggested method 7, "the mutual benefits method of allocation," as apparently meeting the two requirements of equal division among the participants when two companies interconnect and of not reducing the allocated benefit to any of the participating parties with the addition of one or more of the other participating systems to the interconnection.

An allocation of the benefit resulting from the interconnection of three systems has been applied to the conditions set forth in Table I, and the results thereof have been tested by the two previously-proposed basic requirements of a proper allocation. The method of making this allocation and the results obtained therefrom are shown in Table II. These calculations are shown with respect to the capacity benefits computed in the general manner illustrated by Figure 1, which we have termed "the basic capacity benefits," without any adjustment for any additional capacity benefits that may result from the staggering of capacity installations. It is believed that this situation is handled satisfactorily by the procedure suggested in the section called Discussion.

In Table I the allocation has been made on the basis that the portion of the total benefit (that is, the 250-megawatt saving shown as the last item of column 5) allocated to each should be proportional to the sum of the benefits for the various combinations of two's among all the participating systems.

Table II illustrates such calculations. Here the benefit allocated on the suggested "mutual benefits method of allocation" meets the stated requirement that the allocated benefits to any system not be reduced by the inclusion of an additional participating system (comparison of the results shown in the last two lines of the table).

This basis of allocation appears to be equally satisfactory with the inclusion of a fourth participating system, System D, the basic data for which conditions are shown in Table III.

Table II. Allocation of Capacity Benefit to Systems A, B and C

Combinations of Systems by Two's	Benefits for Combinations of Two's A	B	C	Total
A and B, megawatts	65	65		130
A and C, megawatts	75		75	150
B and C, megawatts		170	170	340
Total, megawatts	140	235	245	620
Allocation ratios, per cent (from Totals)	22.58	37.90	39.52	100
Allocated benefits, megawatts	56	95	99	250
Minimum allocable benefits, megawatts	37.5	85	85	

The allocation of the total capacity benefits of 350 megawatts resulting from the data of Table III for this group of four interconnected systems, in the same manner as for the group of three interconnected systems as shown on Table II, is shown in Table IV.

Table V shows data not previously shown for combinations of three's among the four systems considered in Tables III and IV, from which, together with prior data, as related to these various conditions, the allocations of capacity benefits for the various combinations of three's were made in the manner shown in Tables II and IV, with the results shown in Table VI.

Discussion

The tables have shown that "the mutual benefits method of allocation" has met the previously stated requirements for all the conditions studied. It is believed that this result would be ob-

tained for all conditions so long as the installed capacity requirements were determined on the basis of a consistent application of probability methods. Capacity requirements could be assumed or be determined by means other than by an application of probability methods, for which the mutual benefits method might reduce the allocated benefits to one or more of the participating systems with the inclusion of additional systems in the interconnection. If such should occur, it would be the result of inconsistencies of such stated capacity requirements among the various combinations of systems rather than of the method of allocation suggested herein.

It is possible that for certain conditions, particularly those for which there is marked seasonality in the load requirements of some of the participating systems and possibly also with considerable load diversity, that the allocated capacity benefits to one or more of the participating systems may be of such amounts that their resulting capacity requirements would be smaller than their respective most probable annual peak loads. It is not believed that there is anything illogical in such results. Greater reliability would be required of the facilities interconnecting such systems for such conditions than with the other participating systems for which this condition does not obtain.

The same considerations that apply to installed capacity apply also to the allocation of operating capacity benefits. At times the allocation of the operating capacity benefits might also result in the required operation of a smaller amount of capacity by some one or more systems than the amount of their expected loads. Under such circumstance more reliable interconnection facilities would again be required than otherwise.

In practice, the actual capacity installed usually would be greater than that actually required. This would be true of each of the participating systems for separate operation; but for the interconnection as a whole, if the full potential benefits of interconnecting are to be realized, a few of the participating systems and possibly only one would have excess installed capacity and the others would be deficient. This situation requires an adjustment so that the over-all savings may be equitably distributed to all the participating systems. The algebraic sum of these resulting capacity excesses and deficiencies would be equal to the interconnection capacity excess. This interconnection excess should be allocated to each of the participating systems, using the same allocation ratios used to allocate the capacity benefits as shown in Tables II and IV. The deficient capacity systems should be debited with the sum of their respective capacity deficiencies and allocated portions of the interconnection capacity excess, which totals should be credited to the excess capacity systems. Such adjustments could be made either by bookkeeping entries related to capacity or by periodic money settlements. If the latter is to be the practice, a further adjustment would be required to compensate the debit systems where there would be a loss in operating economies because of foregoing the earlier installation of additional economical generating capacity.

Situations may arise where one or more of the participating systems, for various reasons, may desire to install or operate more capacity than that determined as its requirements as a participant. In such case, it alone should be responsible for such additional capacity.

The successful and satisfactory operation of such interconnections require reasonable co-ordination and co-operation among the participating systems, particularly as related to maintenance schedules, which factor is possibly subject to wider control than any of the others that are involved in the determination of the installed capacity requirements. The question as to the loads to be used as a basis for the determination of the installed capacity requirements might present some difficulties. However, these difficulties would be greatly minimized by the use of a mutually agreeable statistical basis for developing the loads to be used for determining the installed capacity requirements. Such a basis would obviate any point of an after-the-fact adjustment for positive load forecasting errors. Such deviations from the forecast loads comprise one of the factors or contingencies for which reserve is provided and consequently their occurrence does not mean

that insufficient capacity was provided any more than if the reduced margin between the available capacity and the load were the result of forced outages of generating facilities. All that is required is that the installed capacity be provided as related to reasonably stable information as related to load forecasts in so far as it is possible to do so, in very much the same general manner as for forced outages of generating facilities.[8] The result is that there would be no more basis or point for hindsight adjustments of the determinations of the capacity requirements after-the-fact with an interconnection than without, which latter is obviously impossible to attain.

There are special situations that may arise that will need to be considered in connection with the actual allocation of capacity benefits that it is not possible to consider in detail in a general paper. For example, the question may arise as to the disposition of the increase, if any, in the firm capacity[4] of the hydro plants that may be available on one or more of the interconnecting systems, that may result from the interconnection. It is believed that such capacity benefits are sufficiently different from the capacity benefits resulting from the interconnection of systems, upon which the installed capacity is all firm, to warrant different treatment to that suggested herein. The same considerations apply to peaking steam capacity. Likewise, after an interconnection is made it is very likely that the participating systems will develop the generating facilities with larger capacity units than if operated separately. This would be more particularly true for the smaller participating systems than the larger. Such a practice would be in line with attaining maximum economy for the interconnecting systems. On the other hand, this practice would tend to result in somewhat higher capacity obligations for the smaller systems than if they continued to install the smaller size units as for separate operation. These increased capacity obligations for the smaller systems, however, are at least largely offset by the greater economies, both as to annual charges per kilowatt of installed capacity and as to operating costs, resulting from the installation of such larger units, which, together with their share of the allocated capacity benefits and of the operating economies resulting from interchange purchases and sales, should, nevertheless, make interconnecting very attractive in many cases, even for the smaller systems.

Likewise, there is the problem as to the allocation among the systems participating in the interconnection of the costs of the interconnecting facilities. This problem is also beyond the scope of this paper, but it would appear that such allocation may well be on approximately the same basis as the allocation of the capacity benefits.

Conclusion

The capacity benefits that result from the interconnection of two or more electric generating systems can best and most logically be evaluated by means of probability methods, and such benefits are most equitably allocated among the systems participating in the interconnection by means of "the mutual benefits method of allocation," since it is based on the benefits mutually contributed by the several systems.

Appendix

After the capacity requirements are adjusted for the allocated computed or basic capacity benefit, two interconnected systems, for which the interconnecting transmission capacity is equal to or greater than half the capacity of the individual units being installed, would require one less unit to be installed 50 per cent of the time, as a matter of chance, as the result of staggering, and still result in the interconnected systems satisfying the combined capacity requirements. This situation results when, without the staggering of the capacity installations, the sum of the installed capacity would be in excess of the indicated combined installed capacity requirements by an amount larger than the capacity of the individual units being installed. The other 50 per cent of the time, the sum of the installed capacity without staggering would be in excess of the indicated combined installed capacity requirements by an amount smaller than the capacity of the individual units being installed, and it is not possible to stagger the capacity installations in such cases.

When staggering is possible, the best results or utilization of the available facilities are obtained when the system with the smaller capacity deficiency continues as the deficient system. In such case the capacity deficiency of the deficient capacity system would range from zero to the smaller of the capacity of the interconnecting transmission facilities and 50 per cent of the capacity of the individual units being installed. The total capacity benefit, for the 50 per cent of the time when staggering is possible, is then equal to the capacity of the individual units being installed and twice the excess of the tie capacity over the capacity deficiency of the deficient capacity system. We then may write

$$y = C + 2(T - x) \tag{1}$$

where

y = the total capacity benefit

C = the capacity of the individual units being installed

T = the capacity of the interconnecting transmission facilities

x = the capacity deficiency of the deficient capacity system

The minimum value of y is C, at which value it remains constant for x equal to T, from T and x equal to zero up to T and x both equal to $C/2$. Since this is the maximum value x can have, y increases thereafter at a 2-to-1 ratio for increasing values of T up to T equal to $(B+C)/2$, where B is the basic capacity benefit with no transmission limitations, determined as discussed in the body of the paper, for which value of T, y is at its maximum value of $(B+C)$. The minimum value x can have is zero, at which value y is again equal to C for T also equal to zero; after which y increases again at a 2-to-1 ratio for increasing value of T, up to T equal to $B/2$, for which y is again at its maximum value of $(B+C)$. These values of y are the boundary values, and they describe a parallelogram as shown by the dash lines of Figure 4. All other values of y for values of x between zero and $C/2$ fall within this parallelogram.

The chances are equal that x will have any value between zero and $C/2$ for T equal to and between $C/2$ and $B/2$. The relative number of occurrences of y for some such value of T is then $(C/2-x)$. We may then weight y with respect to this quantity, as follows

$$y_1 = \frac{\int_0^{C/2}(C/2-x)\{C+2(T-X)\}\,dx}{\int_0^{C/2}(C/2-x)dx} \tag{2}$$

from which we obtain

$$y_1 = \frac{2C}{3} + 2T \tag{3}$$

This means that for values of T equal to and between $C/2$ and $B/2$, the weighted average value of y for the various values of T is two-thirds the distance between the minimum value of $2T$ and the maximum value of $(C+2T)$. For T equal to $C/2$, y_1 is equal to $5C/3$. Then since for T equal to zero, y, and also y_1, are equal to C, we may write for values of T equal to and between zero and $C/2$, assuming a straight line

$$y_1 = C + \frac{4T}{3} \tag{4}$$

This expression also may be obtained in the same general manner as equation 3, as follows, by similarity, for values of T equal to and between zero and $C/2$

$$y_1 = \frac{\int_0^{T}(T-x)\{C+2(T-x)\}\,dx}{\int_0^{T}(T-x)dx} \tag{5}$$

from which we have

$$y_1 = C + \frac{4T}{3} \tag{6}$$

which is identical to equation 4.

Then since for T equal to $B/2$, we have from equation 3 that y_1 is equal to $(2C/3+B)$, and for T equal to $(B+C)/2$, y and y_1 are both equal to $(B+C)$, we may write for values of T equal to and between $B/2$ and $(B+C)/2$, again assuming a straight line

$$y_1=\frac{2}{3}(B+C+T) \tag{7}$$

These values of y_1 of equations 3 and 4 or 6 and 7 are shown by the solid lines of Figure 4.

The weighted average total capacity benefits expressed by equations 3 and 4 or 6 and 7 are available 50 per cent of the time. The other 50 per cent of the time staggering is not possible and for the corresponding conditions for equations 3 and 4 or 6

$$y_1=2T \tag{8}$$

and for the conditions for equation 7, the basic capacity benefit

$$y_1=B \tag{9}$$

For values of T equal to and smaller than $C/2$, the percentage of time the conditions of equations 4 or 6 exist, or for which staggering is possible, is

$$p'=\frac{T}{C} \tag{10}$$

and for which the conditions of equation 8 exist, or for which staggering is not possible, is

$$p''=1-\frac{T}{C} \tag{11}$$

We then may write for the total over-all weighted average capacity benefit, for T equal to and between zero and $C/2$

$$y_2=\frac{T}{C}\left(C+\frac{4T}{3}\right)+\left(1-\frac{T}{C}\right)2T \tag{12A}$$

$$=T\left(3-\frac{2T}{3C}\right) \tag{12}$$

for T equal to and between $C/2$ and $B/2$

$$y_2=0.5\left(\frac{2C}{3}+2T\right)+0.5(2T) \tag{13A}$$

$$=\frac{C}{3}+2T \tag{13}$$

for T equal to and between $B/2$ and $(B+C)/2$

$$y_2=0.5\left(\frac{2}{3}\right)(B+C+T)+0.5B \tag{14A}$$

$$=\frac{5B}{6}+\frac{C}{3}+\frac{T}{3} \tag{14}$$

and for T equal to and greater than $(B+C)/2$

$$y_2=0.5(B+C)+0.5B \tag{15A}$$

$$=B+\frac{C}{2} \tag{15}$$

Equations 12, 13, 14, and 15 are shown plotted on Figure 2, as functions of T, for Systems B and C for which B of the equations is equal to 170,000 kw and for C of the equations equal to zero, 50,000 kw, 100,000 kw, and 150,000 kw.

It is interesting to note that equation 12 is an exponential and that equations 13, 14, and 15 are linear; that equations 12 and 13 are both equal to $4C/3$ for T equal to $C/2$; equations 13 and 14 are both equal to $(B+C)/3$ for T equal to $B/2$; and that equation 14 equals equation 15 for T equal to $(B+C)/2$.

A Method of Estimating Lightning Performance of Transmission Lines

AIEE COMMITTEE REPORT

SINCE the recognition of the direct lightning stroke as the principal factor in causing outages of high-voltage transmission lines during thunderstorms, engineers have sought to obtain and correlate data on the nature of lightning, and to apply such data toward improvements in the design of transmission systems. Such investigations have been pursued through field and laboratory research accompanied by theoretical studies, and remarkable progress has been made in many directions. Indeed, so much has been learned about lightning protection of electric power systems during the past 20 years one might erroneously conclude that the problem has been solved completely.

Many engineers concerned with the design or operation of high-voltage transmission lines have devised methods of combining the known information on the electrical characteristics of lightning with those of the lines so that their performance might be studied more intelligently and that economical methods for reducing lightning tripouts could be developed.

Notwithstanding the rather general appreciation of the fundamental theoretical considerations underlying all these methods, there have been substantial differences in approach and in the application of engineering judgment among well-informed authors.

It is the purpose of this report to present a method of estimating the lightning performance of transmission lines based on collective evaluation of those factors believed to be of greatest significance and incorporating the results of modern methods of analysis.[1] It is the hope of the Lightning and Insulator Subcommittee that a method so evaluated will prove useful to transmission engineers and that any limitations of the method which remain will stimulate the research needed to remove them. In general, one may classify transmission-line lightning protection measures as those whose function is to prevent the initial insulation sparkover, and those whose function is to avoid a line tripout by preventing sustained fault current following such a flashover. This report is confined essentially to those of the first class, although the application of the method to certain types of construction which fall in both classifications will be evident.

Lines Equipped with Ground Wires

It is impractical to provide a sufficiently high impulse insulation level to withstand the voltage which is developed when a phase conductor is struck by any but the weakest lightning strokes whose currents have been recorded. It is therefore of primary importance to employ shield or ground wires located to intercept direct strokes and to divert the lightning current to earth through the steel towers or conductors provided on wood pole structures for this purpose.

The fundamental objective of line designs employing ground wires is to reduce the impulse voltage impressed across any element of insulation between phase conductors and grounded conductors to a value below the impulse flashover voltage of that element. The first step toward meeting this requirement is the use of properly located ground wires. The next step is to devise means of minimizing the voltage which appears across the insulation as a result of the flow of lightning current to earth. Finally, one may investigate whether it is economically feasible to increase the insulation beyond the levels dictated by consideration of switching surges, either by the addition of insulator units or the use of supplementary wood insulation. It is outside the scope of this paper to discuss design features in detail, but certain basic principles and data will be emphasized in order to indicate the factors believed to be of greatest importance in design.

Factors Affecting Insulation Flashover

The principal factors which determine the impulse voltage impressed across any element of line insulation are now well known and may be listed as follows:

1. The magnitude of the lightning-stroke current.
2. The wave shape of the lightning-stroke current.
3. The inductance and ground resistance of towers.
4. The span length.
5. Electromagnetic coupling as influenced by line configuration, conductor spacing, and height above ground.

Some of these factors are influenced by secondary phenomena whose effects can only be approximated in any method of analyzing line performance which is to be of maximum usefulness to the design engineer. These will be discussed later in order to bring out the character of the engineering approximations involved and to indicate lines of further investigation.

Early theoretical investigations of the nature of lightning were concerned with estimating cloud potentials, and were followed by numerous field studies of the

Paper 50-163, recommended by the AIEE Transmission and Distribution Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Summer and Pacific General Meeting, Pasadena, Calif., June 12–16, 1950, and represented at the Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted May 15, 1950; made available for printing May 15, 1950.

This report was prepared by the AIEE Working Group on Methods of Estimating the Lightning Performance of High-Voltage Transmission Lines of the AIEE Lightning and Insulator Subcommittee.

Personnel of the AIEE Working Group on Methods of Estimating the Lightning Performance of High-Voltage Transmission Lines: E. R. Whitehead, *Chairman*, L. V. Bewley, G. D. McCann, Jr., E. L. Harder, S. K. Waldorf, W. W. Lewis.

Figure 2 (right). Configuration of shielding wire and protected conductor for 0.1-per cent exposure

surge voltages impressed on transmission lines either directly or through induction by the lightning stroke. Such a development seemed natural since it is the impulse voltage across insulation which results in flashover or breakdown. Rapid development of travelling wave theory led to the concept of a surge impedance for the lightning stroke. With the analytical possibilities thus enlarged, methods of evaluating line performance were developed[2,3,4] which have contributed greatly to progress in line design. The method presented in this report is necessarily an extension and a refinement of these methods made possible by availability of more data and modern methods of engineering analysis.[5] It is based on the concept that the lightning-stroke current is independent of the terminating impedance which is struck.

Relation Between Factors Affecting Flashover

The general relations existing between the factors listed in the preceding section are also well understood. This relation usually takes the form of an equation which permits a computation of the crest magnitude of the lightning-stroke current necessary to cause sparkover of the insulating element involved. Thus, if normal frequency line-to-ground voltage and other minor potentials between conductor and ground are neglected

$$I = \frac{Vk}{(1-C)P} \tag{1}$$

where

I = crest-stroke current required to cause sparkover
V = insulation flashover voltage from standard curves for 1.5x40 microsecond-wave at a specified reference time lag
P = potential from point struck to ground per-unit stroke current
C = coupling factor in per unit
k = a factor converting V to the estimated minimum flashover voltage for the wave shape of the voltage impressed across the insulation

Once the critical value of stroke current required to cause sparkover thus has been obtained, it is only necessary to determine the frequency with which stroke currents have been found to equal or exceed this value in order to obtain the estimated frequency of flashover.

Upon more careful study it becomes apparent that the factors of equation 1 are in fact interrelated to a considerable extent. For example, the coupling factor is affected by corona on the ground wires, which is in turn dependent upon the ground wire voltage. In the case of a stroke to a tower, the potential P must include the effect of tower inductance even if tower capacitance can be neglected. The problem is even more complicated if a distributed grounding system or counterpoise is employed. Finally the insulation flashover voltage Vk should be the value determined for the particular wave shape impressed, which is itself dependent upon the span length and the ground resistance of adjacent structures.

The considerations just outlined require prohibitive labor if even a moderate range of possible design conditions is to be investigated. Through the use of the electric analogue computer it has been found possible to study a suitable range of line conditions with any desired shape of stroke current. The basic assumptions underlying the present approach to the problem are now discussed.

Lightning-Stroke Characteristics

The magnitude and wave shape of the lightning-stroke current have been recognized as factors of primary importance in the determination of impulse sparkover of line insulation. As a result of several years of field investigations, principally with magnetic links, a relatively large number of measurements of stroke current magnitude have been made available in the literature. These have been combined to give the stroke current magnitude frequency curve of Figure 1. Unfortunately there are insufficient data on the wave shape of stroke current to justify any attempt to establish frequency distribution curves with respect to wave shapes, and it has been necessary to exercise the collective judgment of the working group in the selection of a reference wave shape for the purposes of this report. In making such a selection it seemed desirable to choose both a wave front and a duration such that the resulting calculations would be conservative. Accordingly, a 2x40-microsecond wave shape was initially selected. It has been found, however, that only currents in excess of 30 to 40 kiloamperes are of practical importance on the better-designed lines, and for these currents a 4x40-microsecond wave shape has been chosen as more nearly representative for the purpose of this report. Wave shape is undoubtedly one of the most important and fundamental factors upon which fully adequate data are lacking.

Voltage Wave Shape and Insulation Flashover

In equation 1 the factor P represents the crest potential to ground at the point struck, per unit of stroke current. It replaces the tower-footing resistance R formerly used in this type of equation, and depends upon the tower inductance, the effective structure resistance to ground, the span length, and the wave shape of

Figure 3. Curves for estimating line performance and insulation

The number of equivalent insulators is based upon 10-inch diameter $5^3/_4$-inch spaced units, and the outage probability is based on an isoceraunic level of 30 thunderstorm days per year

Figure 3 (Continued). Curves for estimating line performance and insulation

The number of equivalent insulators is based upon 10-inch diameter $5^3/_4$-inch spaced units, and the outage probability is based on an isoceraunic level of 30 thunderstorm days per year

the stroke current. Furthermore, the wave shape of this potential will in general be quite different from that of the stroke current, rising and falling more rapidly than the current. While calculations of the potential wave are theoretically straightforward, for practical purposes the labor involved is prohibitive. The use of the electric analogue computer in determining both tower and mid-span potentials has been described by Harder and Clayton,[5] and the results of a similar analysis for the 4-microsecond wave front are utilized in this report. In the present analysis tower or structure inductance has been held constant at 20 microhenrys while the tower-footing resistance and span length were varied over suitable ranges. An appropriate insulation spark-over voltage has been estimated from standard curves for suspension insulator units in the case of tower flashover and from extrapolated rod-gap curves in the case of mid-span flashovers through the selection of an equivalent time lag.

Coupling Factor

Through electromagnetic coupling, the potential of the phase wires immediately below the point struck is of the same polarity and proportional to that of the tower or ground wire. Thus the total ground-wire potential does not appear across the insulation, and the ratio of phase-wire potential to ground-wire potential is the coupling factor, C. If no corona is present, the coupling factor is the same whether computed from electrostatic or magnetic quantities if the surface of the earth is taken as a plane of zero potential and zero resistivity, which seems to be a reasonable assumption for conditions at the point struck. If corona is present, the effective radius of the ground wire is increased, and the electrostatic coupling is increased. It is believed that the best approximation to the actual coupling factor under surge conditions is given by

$$C = \sqrt{C_e C_m} \qquad (2)$$

where

C_m = magnetic coupling factor
C_e = electrostatic coupling factor
C = geometric mean coupling factor

C_m is computed using the actual radii of the ground wires and C_e is computed using effective radii of the ground wires as influenced by corona. The effective radii of the ground wires due to corona are given by McCann.[6] In either case the coupling factors are calculated by the equation

$$C = \frac{\log b/a}{\log 2h/r} \qquad (3)$$

where

$C = C_e$ or C_m
b = distance from conductor to image of ground wire
a = distance from conductor to ground wire
r = radius of ground wire
h = height of ground wire above ground

If more than one ground wire is employed, the distances and radius should be replaced by appropriate geometric mean quantities.

Method of Estimating Lightning Performance of Lines

The preceding discussion outlines the theoretical foundation upon which a method of estimating line performance can be based. To be most useful, such a method should be simple in application yet afford a means of adjusting the entering data to conform closely to individual line characteristics. It has been pointed out earlier that effective shielding from direct strokes to the phase conductor is an essential prerequisite to the consideration

Figure 4 (left). Curve for adjusting the number of insulators when the height and spacing of conductors differ from the reference values. Multiply the actual number of insulators by the correction factor

Figure 5 (right). Curve giving total outage probability when the permissible stroke current for mid-span flashover exceeds twice that for tower flashover

Figure 6. Characteristics of insulators and rod gaps

All values are based on positive waves and corrected to standard atmospheric conditions

of other design factors. Moreover, it is known that not every insulation flashover results in power-follow current and an accompanying tripout. Thus there are three parts to the estimating problem:

1. Number of insulation sparkovers caused by strokes to the phase conductor (shielding failures).
2. Number of insulation sparkovers caused by strokes to the ground wire or tower.
3. Number of tripouts caused by 1 and 2.

Figure 1 shows the configuration of the shielding and the protected phase conductor which permits 0.1 per cent of the strokes to terminate on the phase conductor. Good design practice calls for shielding angles of 30 degrees or less in order to allow for hillside locations and in this case even better average shielding should be expected. Because of the vagaries of natural lightning it seems desirable to allow for 0.1-per cent shielding failures even if perfect shielding is indicated.[7]

Strokes to Ground Wire or Tower

Lightning strokes to the ground wire or tower may cause insulation sparkover at the tower, and allowance must be made for the possibility of mid-span sparkover. The latter are believed to be extremely infrequent, particularly on well-designed high-voltage lines. With the aid of equation 1, the electric analogue computer, and standard impulse flashover curves for insulators and rod gaps, the number of standard insulator units or the minimum mid-span clearance required to withstand sparkover for any assigned crest value of stroke current within the range considered may be determined. The frequency of sparkover in a given case then is given by the frequency with which the assigned current value is equalled or exceeded. Figure 1 shows the magnitude frequency distribution curve which has been used in the present study. It is expressed in terms of strokes per 100 miles per year for an isoceraunic level of 30, and has been derived from 3,214 measurements. It is convenient to establish general curves on the assumption that each insulation sparkover is accompanied by power-follow flashover and a line tripout, and to adjust the results for field experience with particular types of line construction. Accordingly, such curves have been prepared for span lengths from 200 to 2,000 feet, covering the ranges of 0 to 100 ohms structure ground resistance, 2 to 26 insulator units, 2 to 200 kiloamperes stroke current, and 0 to 20 outages per 100 miles per year. Two sets of curves are shown for each span length, one giving the estimated

Figure 7 (left). Impulse insulation added to insulator strings by wood

Equivalent insulators to be added may be determined from Figure 6

Figure 8 (right). Effect of current on impulse resistance of driven ground rods

Figure 9. Isoceraunic map showing number of thunderstorm days per year

outages per 100 miles per year as determined by the curve of Figure 1, and the other giving the permissible stroke current for use with more accurate stroke current distribution data which may be available for a particular region under consideration. Curves (A) to (H) of Figure 3 apply for strokes to the tower, while curves (I) and (J) apply for strokes to mid-span.

The outage curves are based on a line configuration which involves a 28-foot separation between a ground wire at a reference height of 75 feet and the most distant phase conductor. If the actual ground wires are at a different height or the geometric mean distance from the ground wires to the most distant phase conductor is other than 28 feet, the actual number of insulators should be multiplied by the correction factor from Figure 4 to obtain the number of insulators with which to enter the curves. The influence of corona on the coupling factor has been included as indicated in equation 2 through the use of effective radii as determined by McCann[8] for the electrostatic coupling factor. In the case of strokes to mid-span, it has been necessary to extrapolate the available data. Increasing coupling factors have been used up to 8 megavolts, but they have been held constant to assure conservative results for voltages above this value.

The reference value of tower inductance has been taken as 20 microhenrys. This is believed to be a conservative value, since it corresponds approximately to a steel tower 100 feet high or to a wood pole 50 feet in height with a ground conductor having an inductance of 0.4 microhenry per foot. It is not possible to give accurate correction factors to modify the indices of Figure 3 for other values of inductance which are applicable to all span lengths, but Figure 11 has been included to indicate the influence of inductance on the number of insulators required in the case of a 1,000-foot span and a 2x40-microsecond wave of 50-kiloampere crest.

Figure 6 shows the standard impulse flashover characteristics for insulators and rod gaps upon which the general curves are based. On wood pole lines and certain types of steel tower construction, the impulse insulation may consist of porcelain and wood in series. Figure 7 gives the insulation which may be added to that of the porcelain alone when supplementary dry wood insulation is employed. It

Figure 10 (left). Comparison of estimated performance with experience

Figure 11 (right). Effect of tower inductance on number of insulators required for a 2x40-microsecond wave of 50-kiloamperes crest

Figure 12. Transient impedance of counterpoise systems

should be noted that the addition decreases with the time to flashover and with the length of the insulator string. Moreover, it has been found that moisture may substantially reduce the impulse insulating value of wood insulation, particularly at the longer time lags.[8] If more accurate data are not available, each foot of wood may be taken as equivalent to one insulator unit if dry, and as equivalent to one-half unit if wet. If the limiting insulation is an air gap, the equivalent number of suspension insulator units may be obtained readily from Figure 6.

Strokes to mid-span may cause tower flashovers if the permissible stroke current for mid-span flashover exceeds twice that of the tower. With small error, the outage probability for such strokes can be combined with that for strokes to the tower to give a single outage probability curve for all strokes to the ground wire. Figure 5 shows the curve to be used in these cases.

Applications of the Estimating Curves

The estimating curves may be used to compare the relative performance of proposed transmission-line designs or to determine the probable effect of modifications to existing lines. It is in such applications that their greatest value lies. Nevertheless, they have been prepared in such a way that, with the help of additional data, they may be used to estimate the actual average performance of lines. Figure 9 shows an isoceraunic map[14] which gives the average number of thunderstorm days per year for the United States and part of Canada. The general outage probability curves are based upon 100 strokes to the line per 100 miles per year for an isoceraunic level of 30.

Three examples will be given illustrating their use.

Example 1

A 138-kv steel tower line, shielded by an overhead ground wire, located in territory with an isoceraunic level of 50, has ten $5^3/_4$-inch spaced insulators per string. The average span is 1,000 feet and the mid-span clearance is 24 feet. The tower-footing resistances are 10 ohms for 20 per cent of the towers and 20 ohms for 80 per cent of the towers. What is the outage probability for this line? From Figure 3(E) for 1,000-foot spans, the outage probability for 10 ohms and 10 insulators is 0.7 outage per 100 miles per year. For 10 insulators and 20 ohms the figure is 2.8. The combined probability for strokes to tower is $(0.7\times0.2)+2.8\times0.8)=2.38$ per 100 miles per year. The permissible stroke currents for the 10 and 20 ohms are 124,000 and 79,000 amperes respectively.

From Figure 3(I) the outage probability is 0.6 per 100 miles per year for 1,000-foot spans with mid-span clearance of 24 feet. The permissible stroke current is 128,000 amperes. The average of 2.38 and 0.6 is 1.49 for an isoceraunic level of 30. The outage probability for the given isoceraunic level of 50 is 50/30 times 1.49 or 2.48 outages per 100 miles per year. This computation assumes perfect shielding and would be increased to approximately 2.65 for 0.1-per cent shielding failures.

Example 2

A 33-kv wood pole line, shielded by ground wire, located in territory with an isoceraunic level of 30 has two $5^3/_4$-inch spaced insulators per string. The minimum flashover path is the porcelain plus four feet of wood. The average span is 200 feet and the mid-span clearance eight feet. The tower-footing resistance is 50 ohms for all poles. The distance between the ground wire and bottom conductor is 10 feet at the tower. What is the outage probability for this line?

From Figure 7 four feet of wood is estimated as adding 450 kv to the insulation strength of the porcelain. Thus the total equivalent insulation is 6.0 units. Since the spacing from ground wire to conductor is considerably less than 28 feet, an adjustment is needed to compensate for increased coupling.

From Figure 4 the correction factor for a 10-foot spacing is 1.2 and the effective insulation becomes $6\times1.2=7.2$ insulators. From Figure 3(A) the outage probability for 7.2 insulators and 50 ohms footing resistance is 5.4 outages per 100 miles per year. The permissible stroke current is 62,000 amperes. From Figure 3(I) the outage probability for strokes to mid-span for a 200-foot span and 8-foot clearance is 0.0 per 100 miles per year and the permissible stroke current is 200,000 amperes.

Since the permissible stroke current for mid-span flashover exceeds twice that for strokes to the tower, the total outage probability should be taken from Figure 5. The permissible stroke current to a tower is 62,000 amperes, for which the total outage probability is read as 3.1 per 100 miles per year. This figure assumes that all insulator flashovers result in tripouts. Experience with such lines indicates that approximately 50 per cent of the flashovers will result in tripouts, so that the final estimate is $0.5\times3.1=1.6$ outages per 100 miles per year for this line. This estimate assumes perfect shielding and would be increased to approximately 1.65 for 0.1-per cent shielding failures.

Example 3

A transmission line is to be constructed in a territory where the isoceraunic level is 30. The line will be shielded by ground wire and it is desirable to insulate the line so that outages due to lightning will be limited to 2.0 per 100 miles per year. Knowledge of existing lines in the territory indicates that tower-footing resistances of 20 ohms can be obtained economically. The choice of towers and conductors calls for an average span of 800 feet. The conductors and ground wire will be

sagged to provide a mid-span clearance of 18 feet. How many insulators are required to effect the desired limitation on outages?

From Figure 3(J) the outage probability for strokes to mid-span is 0.6 outage per 100 miles per year. The outage probability for strokes to tower must be 3.4 if the average is to be 2.0 per year. From Figure 3(D) 8.5 insulators are required for the outage probability of 3.4 if the footing resistance is 20 ohms. Thus nine insulators should limit the outage probability to 2.0 per 100 miles per year.

Outage Estimates and Field Experience

Although the estimating curves are most valuable for comparative purposes, it is believed that they give results consistent with practically all of the published results on actual line performance. In general it is known that 33-kv lines with a basic insulation level of 700 kv and 10 ohms footing resistance result in two or three outages per 100 miles per year. The 132-kv lines designed for good lightning performance will have about one outage, while modern 220-kv lines will have only a small fraction of one outage per 100 miles per year. The latter are often referred to as lightning-proof. Figure 10 shows a comparison of published performance with estimated performance.[13] The estimated performance necessarily is based upon average tower-footing resistance obtained by low voltage measurements. If the distribution of towers having various footing resistances is known, a much more accurate estimate results.

Factors Limiting Accuracy of Estimates

In the evaluation of essential factors affecting the problem, the working group has been fully aware of the uncertainties existing with respect to many of the primary data employed. Moreover, there remain certain points upon which little, if any, research has been conducted. While a few of these have been indicated in appropriate preceding sections, it appears desirable to list the more important ones here. It is quite likely that at least some of these uncertainties tend to offset each other in the end result, and that improvement with respect to one factor would necessitate a corresponding improvement in another. The principal sources of uncertainty with respect to the data employed in constructing the general curves and in the data necessary to use these curves will be discussed.

Variability of Tower Footing Resistance

The estimating curves are based on a constant value of resistance located at the base of the tower. If the resistance has been secured by means close to the tower but is higher than approximately 10 ohms, the resistance to high lightning current may be substantially lower than the 60-cycle value. No correction factors are available for common grounding systems at the significant lightning currents, but Figure 8 shows how the resistance of driven ground rods varies with current.[10]

Effect of Distributed Grounding or Counterpoise Systems

The performance of distributed grounding systems, commonly called counterpoises, has been reported in the literature.[9,10,11,12] Figure 12 shows how the impedance of a counterpoise grounding system varies with time. Since such systems usually extend in both directions from a tower, N may be taken as 2.

For the 4-microsecond wave front of current upon which the general curves are based, it appears satisfactory to use the measured leakage value of the grounding system if this resistance is secured with a total length of buried conductor of 1,000 feet or less per tower. Further comment on this point is made in the section on Current Wave Shape.

Current Wave Shape

Because of the rapid reduction of ground-wire voltage caused by the reflections from adjacent towers, the duration of the tail of the current wave does not greatly influence insulator flashover. However, the wave front of the current wave is of the greatest significance. Unfortunately there are insufficient data upon which to base a really satisfactory distribution curve for wave fronts and in an effort to make the results conservative, a wave front of two microseconds was initially selected for the purpose of the present study. As the investigation proceeded it became apparent that only the higher currents, in excess of 30 kiloamperes, were of especial importance. For these McCann[18] has found that the median value is approximately four microseconds. The use of such a wave front brings the estimated performance more closely into agreement with field experience with respect to mid-span flashovers. The choice of a single wave front, although desirable for simplicity in the development of general curves, cannot be regarded as entirely satisfactory. Occasionally one must expect to have lightning currents whose rate of current rise is sufficiently high to cause flashover either at the tower or at mid-span which would not be indicated from the curves presented.[11]

Table 1. Summary of Anacom Study

Span, Feet	Tower Foot Resistance, Ohms	Tower-Top Voltage Per Ampere of Stroke Current	Mid-Span Voltage Per Ampere of Stroke Current	Time Lag to Insulate Microseconds

Stroke Current Magnitude

The magnitude distribution curve of Figure 1 has been derived from 3,214 measurements using magnetic links. The sum of the currents in adjacent towers has been taken as the stroke current. Individual tower currents were determined by addition of currents in all tower legs where such measurements were made, or by multiplication of partial measurements, assuming current distribution in the tower legs.[9] Tower currents so deter-

mined are likely to be too low, since they do not include the current carried by the cross braces. On the other hand, the method of deriving the stroke current results in values which may be in error on the high side to a comparable degree. Moreover, stroke currents which have been directly measured are in quite good agreement with Figure 1. For these reasons the working group has adopted this curve as satisfactory for estimating purposes.

Ratio of Outages to Flashovers

All lightning flashovers do not result in sustained power-follow current and an accompanying line tripout. Performance records on various types of lines give some information on the ratio of outages to flashovers.[16,17] For high-voltage steel tower lines the ratio is 0.85 for lines under 100 miles in length. This ratio may decrease to 0.5 for lines over 200 miles in length. In the case of wood pole lines where the flashover path may include wood members, the ratio of outages to flashovers ranges from 0.35 to 0.50.

If the characteristics of the line and its insulation result in a substantial reduction of the ratio of outages to flashover, this ratio should be included in the final estimate of the outage probability. If, however, the ratio is near unity, it well may be neglected and the general curves used directly to give conservative results.

Other Line Potentials

In the preparation of the general curves, no account has been taken of the normal frequency voltage, nor has consideration been given to any potential which may exist on the phase conductor as a result of electromagnetic induction from the stroke itself. While this uncertainty may represent an area inviting future research or analysis, it is felt that it does not represent a factor which seriously affects the relative usefulness of the method presented.

Conclusions

This report represents the results of a study of various methods of estimating lightning performance which has been made by a working group of the AIEE Lightning and Insulator Subcommittee. The essential factors of the problem have been carefully considered and have been incorporated into a method which, it is hoped, will be of value to those concerned with the design of new lines or the modification of old ones. Various phases of the result involve considerable uncertainty and these have been discussed briefly in order that the character of the approximations adopted may be better understood.

Discussion

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper should be of considerable help to the industry in evaluating lightning performance of transmission lines. As pointed out in the paper many of the factors involved in the calculations are known only approximately. One of these is the amplitude of the lightning stroke current and its wave shape.

Measurements of tower current amplitudes by Lewis and Foust, Waldorf, and Grünewald in Germany, result in frequency curves of almost exactly the same shape. A total of 6,377 measurements are involved. It would seem, therefore, that these curves should approach very closely the true frequency distribution of lightning current amplitudes in towers. This curve is considerably below the curve of Figure 1 of the report which gives lightning stroke currents calculated from tower current measurements.

For instance, 5 per cent of the tower currents are 40,000 amperes as compared to 62,000 for the assumed lightning stroke currents. The maximum tower current is of the order of 140,000 amperes as compared to 200,000 amperes lightning stroke current.

Calculations made some time ago[1] indicate that lightning stroke currents are only slightly higher in amplitude than the current in a tower which was struck. This also is substantiated by measurements of the lightning stroke currents in series with transmission towers by means of lightning rods extending beyond the towers. Frequently tower currents and lightning rod currents are alike. Therefore, the frequency curve given in Figure 1 of the report should give pessimistic results. In the case of strokes to midspan, of course, the currents measured on the ground wire should be added up to give total current.

The sparkover characteristic curves shown in Figure 6 do not give the complete story of sparkover in the nonuniform field. It has been shown[2] that sparkover depends greatly on the type of the wave shape applied. For instance, for a 50-inch gap, sparkover may be as low as 1,130 kv for a rectangular wave and as high as 1,630 kv for a straight rising front. The type of voltage wave to be expected at any part of the system depends on the relative values of inductance and resistance in the discharge path. At midspan, the usual case of high inductance and low resistance would produce a rather steep front and very short tail wave corresponding more nearly to the straight rising front condition. For sparkover at 2 microseconds, this would give approximately 330 kv per foot or more to obtain sparkover.

Nevertheless, the examples of Figure 10 show very good correlation between calculated performance and experience.

E. R. Whitehead: The points brought out in Mr. Hagenguth's discussion are indeed pertinent and received the careful consideration of the working group in establishing the set of approximations upon which to base the method. The greatest single difficulty is that adequate treatment of these and other factors awaits a degree of knowledge of the wave shape of the lightning current roughly comparable to that concerning the current amplitude.

In its early approach to the problem, the working group recognized two general trends of thought. On the one hand, it appeared desirable to base the method on a very few factors whose influence was firmly established and on which the greatest volume of data was available. On the other hand, it seemed important that the method make the fullest possible use of modern knowledge relating to other factors such as Mr. Hagenguth has mentioned. Study of the latter course soon brought out that the analytical tools and general appreciation of these factors were far ahead of the available data essential for their practical use. Thus, the report of the working group represents its current evaluation of the weight to be accorded the various theoretical considerations in a method which, it is hoped, will be of value to designers of transmission lines.

Theory and Application of Transformer Differential Protection

GEORGE W. McKENNA
ASSOCIATE AIEE

Synopsis: In attempting to use standard percentage differential relays for transformer protection in the most efficient manner for a wide variety of transformer connections and types, several problems have arisen which have resulted in solutions not in the usual repertoire of transformer protection. The scope of this paper is limited to some general remarks on the fundamentals of transformer protection using percentage differential relays, and to a few selected applications of this type of relay which depart somewhat from the usual course of such protection. Certain occasional and independent problems of transformer protection which are superimposed on the basic application requirements to be discussed here, such as relay operation on transient magnetizing inrush current flow, are not included within the scope of this paper.

The Principles of Differential Protection

THE usual statement of Kirchhoff's law concerning current flow found in the standard text books is "The sum of the currents coming toward a junction of conducting branches of an electric circuit is equal to the sum of the currents leaving that same junction." For protective relaying purposes this law can be restated as "If all the currents flowing into and out of the junction or region of an electric circuit through all the legitimate paths are added together and do not equal zero, then there exists one or more improper paths to the junction which represent failures of insulation." The term "failures of insulation" is often replaced by such terms as "faults," "short circuits," or "breakdowns," all of which describe the same electrical misadventures.

Figure 1 depicts the functioning of Kirchhoff's law in differential relaying. Figure 1 (A) represents the general statement of the law. Figure 1(B) places the junction inside a transformer or other device and adds, in relay R, the current flow to and from the junction through current transformers of ratios which match the voltage transformation ratios of the transformer. Figure 1(C) shows that any unorthodox current to the junction, I_z, which is not included in the current summation, would cause a proportionate current to appear in the relay R. Since I_z is fault current relay R can instantly detect a fault in the region bounded by the current transformers, while any such unaccounted-for current beyond the current transformers would have no effect on the summation of the measured currents to zero in the relays as shown in Figure 1(B). This sharp definition of internal faults for which the relay should operate and external faults for which the relay should not operate enables the relay to be made to operate without any intentional time delay (operating time approximately 3 to 6 cycles on a 60-cycle basis).

The Percentage Differential Characteristic

In order to use an unmodified current relay to detect the difference between incoming and outgoing currents in a transformer, two requirements must be met. First, the current transformer ratios must exactly compensate for the transformation ratio of the power transformer so that the secondary currents can be added directly at the relay just as if the transformation ratio were unity. Second, this compensation in ratios must be maintained throughout the entire range of external fault and load currents to prevent the relay from operating incorrectly. Both of these requirements are often difficult, if not impossible, to achieve.

In the general case the necessary current transformer ratios for exact ratio compensation would be anything but standard so that tailor-made current transformers would have to be built for each job at a considerable sacrifice in economy. With transformers with variable ratios, such as those equipped for tap changing under load, the problem of exact compensation is almost practically insuperable.

Generally the current transformers on opposite sides of a transformer must have different turn ratios to match the transformer turn ratio and for this reason the current transformers might behave differently under high external fault currents. Thus, while ratio compensation might be attained completely at low values of current, it might be lacking at the higher values even though the currents in the power transformer leads continued to adhere to the power transformer transformation ratio. Thus an "error" current, which gives the appearance of a fault in the transformer when there is no such fault, will flow through the relay of Figure 2(A) and this current could easily be of such a magnitude as to cause the relay to operate incorrectly.

In order to allow for incomplete compensation and thus permit the use of current transformers of standard ratios and of slightly different behaviour characteristics the percentage differential relay was developed as shown in Figure 2(B). This relay has three coils; current through coil O produces a torque in the contact-closing or operating direction and coil O is thus called the "operating" coil; currents through coils A and B produce a torque in the contact-opening or restraining direction and for this reason these coils are called "restraining" coils.

In order to allow even greater freedom

Paper 50-189, recommended by the AIEE Relays Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted June 19, 1950; made available for printing September 7, 1950.

GEORGE W. McKENNA is with the Philadelphia Electric Company, Philadelphia, Pa.

Figure 1 (left). Kirchhoff's law and differential relaying

Figure 2 (above). Differential relays

in the choice of current transformer ratios, taps are provided on the operating coil and one restraining coil so that while an unbalance current might flow through the operating coil circuit due to incomplete ratio compensation, the ampere turns can be balanced to provide compensation on a flux basis rather than on a current basis.

The effect of the restraining coils is to make the operating current for pickup of the relay depend directly on the amount of restraint current, which reflects in turn the current level in the power transformer itself. For low currents in the power transformer the required pickup current in the operating coil is low, while for large currents in the transformer the operating current must be correspondingly higher. The pickup current of such a relay is expressed as a percentage of the smaller restraining current with the term "slope" sometimes used as a synonym for sensitivity. This percentage characteristic, as compared to the single value of pickup current in amperes for the differentially connected overcurrent relay of Figure 2 (A), is primarily designed to allow for variation in current transformer behaviour which produces larger error currents for larger values of primary current.

Figure 3 shows how a 25-per cent slope characteristic takes care of a 10-per cent error in the ratio of a set of 500/5-ampere current transformers in the case of an external fault for which the transformer protective relay should not operate.

Analysis of Differential Relay Operation

In the application of percentage differential relays for transformer protection it is necessary to calculate the behaviour of the relays under external fault conditions for all possible variations in the transformer operation, such as those due to tap changing under load. The percentage characteristic allows a certain deviation from perfect ratio compensation and it is necessary to determine how much of that allowable deviation is used up in order to determine how close the relay is to operation under external fault conditions.

The percentage differential relay for transformer protection has taps as indicated in Figure 2(C) to allow for a wide choice of current transformer ratios and the effect of these taps must be taken into consideration. The tap range usually allows for a variation in current transformer ratios up to at least twice that required for perfect ratio compensation. Figure 4 shows how these taps are used in a 50-per cent slope relay. With the tap associated with the restraint coil A set at 5 amperes and the tap for restraint coil B set at 10 amperes, the compensation at the relay is perfect in spite of the fact that the total operating current in amperes (25 amperes) is 100 per cent of the smaller restraining current and the relay has a 50 per cent characteristic for operation. The perfect compensation is brought about not by balancing amperes but by balancing ampere turns. It appears reasonable, then, that all calculations of differential relay operation should be made in terms of ampere turns rather than in terms of amperes. This procedure becomes imperative in case the phase angle between the currents in coils A and B is neither zero nor 180 degrees.

In Figure 4, with the tap settings previously stated, 50 amperes in coil B and out through the operating coil produce the same ampere turns as 25 amperes in coil A and the operating coil, and with the current flow as shown for an external fault the operating ampere turns cancel exactly producing perfect compensation. This is because the operating coil turns through which the current from the 200/5-ampere current transformer flows are twice as many as those through which the current from the 500/5-ampere current transformer flows.

The difference in turns can be taken care of for calculation purposes by obtaining the equivalent currents on an *equal tap* basis, which can be done by multiplying the current in coil B by the ratio of the tap for coil A divided by the

(A) OPERATION OF DIFFERENTIALLY-CONNECTED OVERCURRENT RELAY DUE TO CURRENT TRANSFORMER ERROR

(B) PREVENTION OF INCORRECT RELAY OPERATION BY RESTRAINT COILS

Figure 3 (left). Effect of current transformer ratio error

Figure 5 (above). Over-all protection of transformer and phase shifter

tap for coil B. Expressed as a formula

$$(I_B)\text{equiv} = I_B(T_A/T_B) \qquad (1)$$

where $(I_B)_{\text{equiv}}$ is the equivalent current in coil B for equal tap settings of T_A and T_B; I_B is the actual current in coil B; T_A and T_B are the tap settings associated with coils A and B, respectively.

Once the currents are transformed to an equal tap basis the difference in coil turns is taken care of and the relationships of the transformed currents can be compared directly with the percentage slope of the relay to determine whether the relay will operate correctly with a reasonable safety margin or not. Using this particular method of analysis it is necessary only to remember to base the per cent unbalance under actual fault conditions on the smaller of the two restraint currents after transformation by the tap ratio (T_A/T_B). Other methods are possible but many of these involve two formulas from which the proper choice must be made based on relative current magnitudes. The equivalent current method based on equation 1 is very useful in calculating the margin of safety for a differential relay where the restraint currents are neither in phase nor 180 degrees out of phase.

Protection of Transformer and Phase Shifter

A problem which arose concerning the over-all percentage differential protection of a 20,000-kva 69–13.8-kv transformer and a 13.8-kv phase shifter for load flow control may be of value in pointing out the worth of the equivalent current method. The transformer, the current values involved, and the tap settings used are shown in Figure 5. The phase shifter and the transformer with

Figure 4 (left). Ratio compensation with aid of relay taps

(B) WYE-DELTA UNGROUNDED TRANSFORMER BANK

Figure 7. Protection of Y-delta transformer banks

tap changing under load acted in concert to maintain a constant voltage ratio between the 69-kv line and the 13.8-kv bus regardless of the phase angle between the voltages and currents at those two points. The maximum shift introduced by the phase shifter was approximately 14 degrees.

The first step in the analysis was to get the secondary currents on an equal tap basis. From equation 1

$$(I_B)_{equiv} = I_B(T_A/T_B) = 4.20(5/6) = 3.50 \text{ amperes}$$

Comparing an equivalent $I_B = 3.50$ amperes with an I_A of 2.92 amperes it can be determined that with no shift due to the phase shifter the operating current I_0 would be 0.58 ampere or an unbalance of $0.58/2.92 \times 100 = 19.8$ per cent compared to the pickup unbalance (slope) of 50 per cent, indicating a satisfactory margin of safety.

When the maximum 14-degree phase shift occurs, however, the operating current must be obtained by vector subtraction and the total restraining effect by a vector addition of the restraining currents. It can be deduced from the percentage slope characteristics that for a 50-per cent slope relay the pickup current distribution on an equal tap basis is one unit of current in the operating coil to two units of current in one restraining coil and three units of current in the second restraining coil, as shown in Figure 6. It can be assumed that at pickup the operating ampere turns equal the restraining ampere turns. From this assumption and the current distribution it follows that the operating coil must have five times as many turns as either restraining coil. It also would appear from the design of the relay that the total restraint flux is the sum of the fluxes in the individual restraint coils, or the total effective restraining current is the vector sum of the individual currents in the restraining coils. By comparing this total effective restraining current with five times the operating current (the factor of five takes care of the greater number of turns in the 50-per cent characteristic relay) the tendency toward operation can be evaluated.

In the problem of Figure 5, with the maximum 14-degree phase shift, the restraint currents can be expressed as $2.92 + j0$ amperes for I_A and $3.39 + j0.85$ amperes for $(I_B)_{equiv}$. By subtraction, the operating current is thus $0.47 + j0.85$ amperes. The operating ampere turns are proportional to $5\sqrt{(0.47)^2 + (0.85)^2} = 4.86$. The total effective restraining current is the sum of the two individual restraint currents or $6.31 + j0.85$ amperes and the restraint ampere turns are proportional to $\sqrt{(6.31)^2 + (0.85)^2} = 6.37$. Since an equality between operating and restraining ampere turns represents pickup of the relay, as does the percentage slope figure of 50 per cent, the actual unbalance with the 14-degree phase shift is $4.86/6.37 \times 50$ per cent $= 38.2$ per cent. This unbalance figure of 38.2 per cent with the 14-degree shift compared to the 19.8 per cent unbalance without the shift clearly demonstrates the necessity of the vector treatment of the restraining and operating currents. The 38.2 per cent unbalance leaves a rather small margin of safety under the 50 per cent pickup value but the power transformer taps shown in Figure 5 represent the worse possible combination and will not normally be used.

Protection of Y-Delta Transformer Banks

In the passage of current through a Y-delta transformer bank it is well known that a shift of 30 degrees takes place in the phase angle of the line currents and it is also well known that the proper current transformer connections for differential relays can compensate for this shift. The rule is that current transformers on the Y side of the transformer bank should be connected in delta while those on the delta side should be connected in Y, as shown in Figure 7(A).

A transformer installation as shown in Figure 7(A) was planned and, of course, the foregoing rule was to be followed in the connection of the current transformers feeding the percentage differential relays. Prior to this installation, however, a temporary bank was to be used which had to be connected Y-delta where the permanent bank was to be delta-Y. It was hoped that the change from the temporary bank to the permanent bank could be made without complicated and costly changes in the connections from the current transformers to the relays, which would have been necessitated by a strict adherence to the rule expressed before. It was found that if the Y-connected windings did not have their neutral grounded, the rule could be broken with impunity and the final relay connections could be used without alteration with the temporary bank, as shown in Figure 7(B).

The justification behind this infraction of the rules lay in the fact that the phase angle shift in the line currents could be compensated for by either Y-delta or delta-Y current transformer connections; that the delta connection had to be used on the grounded side of the bank to trap zero sequence currents coming from the ground for external faults, and that if the Y side of the bank were not grounded this trapping effect was unnecessary and the current transformers could be connected Y-delta or delta-Y with complete freedom of choice. A more mathematical justification of the unorthodox connection of Figure 7(B) is given in Appendix I of this paper.

Protection of Paralleled Y-Delta and Delta-Y Transformer Banks

It has been proposed that a pair of paralleled banks, connected delta-Y and Y-delta with common high and low side

circuit breakers, protected by a single set of differential relays, have both Y-connected windings grounded, giving the connections shown in Figure 8(A).

This poses somewhat of a dilemma in that the current transformers must be connected Y-delta to compensate for the 30-degree shift in line currents while the presence of the grounds on both sides of the transformer banks dictates, according to the rule, the use of delta-delta connected current transformers which would make the 30-degree compensation impossible.

Since the Y-connected current transformers are by themselves unable to keep zero sequence operating current out of the differential relays for external ground faults, which trapping effect delta-connected current transformers can produce with ease, some external zero sequence trap must be provided to "suck away," as it were, the disturbing zero sequence current from the relay. This can be done by using the zero sequence current in the neutral itself to cancel out the zero sequence current which emits from the Y-connected current transformers for an external ground fault. All that is needed to accomplish this result is a current transformer in the transformer neutral and one auxiliary current transformer per phase to inject the neutral current into the relay current circuits as outlined in Figure 8(B).

The basis for this additional current circuit lies in the Kirchhoff law requirement for measuring the current in every legitimate path to the transformer, and the neutral connection to ground represents such a path.

Protection of Scott-Connected Transformer Banks

The protection of Scott-connected 3-phase to 2-phase transformer banks is generally accomplished by a relay scheme with connections as shown in Figure 9(A). The reversal of the B-phase current transformer on the 3-phase side should be noted. Because of this reversal there is current flowing under normal load conditions in all three connections from the 3-phase current transformers to the relays, such as at points 1, 2, and 3. If the 3-phase side of the Scott bank is ungrounded a ground overcurrent relay on the 3-phase side can be used to good advantage because it can be set with a maximum of sensitivity since it can get the current it requires for operation only if a ground fault occurs between its current transformers and the bank, or in the 3-phase windings themselves. Such a relay would be insensitive to ground faults on the 3-phase system outside this restricted zone and insensitive also to all 2-phase faults.

However, with the 3-phase current transformer connections of Figure 9(A) there is no place in the current transformer secondary circuit where a ground relay can be introduced, since there is no point where ground current can flow without there also being considerable phase current to confuse the relay.

Using the relay scheme of Figure 9(B)

Figure 8 (below). Protection of paralleled Y-delta banks

Figure 9 (right). Protection of a Scott-connected transformer bank

(A) TRANSFORMER BANK CONNECTIONS

(B) RELAY CONNECTIONS (ONLY ONE PHASE SHOWN)

(A) USING REVERSED B-PHASE CURRENT TRANSFORMER

(B) USING MID-TAPPED AUTOTRANSFORMER T

of which the vital element is the mid-tapped autotransformer T, the residual circuit of the 3-phase current transformers is preserved and the ground relay can be introduced into this circuit as shown in Figure 9(B). The autotransformer mixes the currents from phases A and B on the 3-phase side so that the mixture can properly be compared in the differential relay with the current from the current transformer in the A phase on the 2-phase side.

Conclusion

By going back to the basic principles of transformer protection with percentage differential relays the scope of application and the efficiency of protection of such relays can often be increased with little or no sacrifice in economy.

It is suggested in this paper that the mathematical analysis of the operation of percentage differential relays for transformer protection be based on a conversion of the currents involved to an equal tap basis. In this manner the complicating effects of the use of different taps and coil turns can be removed early in the calculations by a straight forward process.

Where the two restraining currents are neither in phase nor 180 degrees out of phase the necessity of the vector determination of both the operating current and the total restraining effect is pointed out.

Appendix I. Protection of a Y-Delta Transformer Bank as in Figure 7(B)

Let I_A, I_B, I_C be the currents in the Y-connected windings of the transformer.

Assuming, for purposes of this demonstration, a power transformer winding ratio of unity, the currents in the delta-connected windings are also I_A, I_B, and I_C, while the line currents on the delta side are I_A-I_C, I_B-I_A, and I_C-I_B.

The current transformers of the delta side are also delta-connected so that the currents fed to the differential relay are proportional to

$$(I_A-I_C)-(I_B-I_A)$$

$$(I_B-I_A)-(I_C-I_B)$$

and

$$(I_C-I_B)-(I_A-I_C)$$

The currents from the Y-connected current transformers on the Y side of the power transformer are proportional to I_A, I_B, and I_C. Connections should be made to feed I_A from the Y-current transformers, denoted as $(I_A)_Y$, to the same relay element to which is fed $(I_A-I_C)_\Delta-(I_B-I_A)_\Delta$ from the delta current transformers, which origin is indicated by the subscript "Δ." For this to be a correct connection it must be proved that

$$n(I_A)_Y=(I_A-I_C)_\Delta-(I_B-I_A)_\Delta$$

where n is a proportionality factor which affects only the current transformer ratios and not their connections.

The proof of the correctness of the foregoing mathematical assertion can be demonstrated as follows

$$n(I_A)_Y=(I_A-I_C-I_B+I_A)_\Delta$$

$$n(I_A)_Y=(2I_A-I_C-I_B)_\Delta$$

$$n(I_A)_Y=(2I_A+I_A-I_A-I_B-I_C)_\Delta$$

Since the Y-connected power transformer winding is ungrounded

$$-I_A-I_B-I_C=0$$

Therefore

$$n(I_A)_Y=3(I_A)_\Delta$$

and thus with the proper current transformer ratios the foregoing connections of Figure 7(B) are correct. It should be noted that the key circumstance is the lack of a neutral ground on the Y-connected side of the power transformer bank.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): It may be of historic interest to mention that the relay connection on the right side of Figure 8(B) was analyzed and used in Europe some 25 years ago in at least two installations.

One of them concerned a new 110-kv system that had been designed to be operated resonant grounded, with Petersen coils installed at the receiving ends of two circuits, fed from a large hydroelectric plant where the transformer neutrals would be isolated. Differential protection of these transformers was obtained by using only two current transformers on the 110-kv side and three current transformers on the delta-connected low-voltage side, and this saving necessitated delta connection of the current transformers on the low-voltage side also. Because of a delay in the installation of the Petersen coils, however, the system was in operation with the neutrals of two transformers solidly grounded in the power plant for approximately one year. A third current transformer on the 110-kv sides and current transformers (of greatly reduced voltage class) in the transformer neutrals were added temporarily to produce neutralization of the zero sequence currents in the neutrals. After the solid grounding of the 110-kv system was changed to resonant grounding as originally planned, the additional current transformers were removed. Those temporarily on the 110-kv sides were used with the transformer of the third generator unit that was added later.

A similar installation of differential protection was made in another 110-kv system that was designed for operation with solid neutral grounding. The connection of the current transformers in wye and delta respectively on the high-and low-voltage sides, was the preferred choice for reasons beyond the control of the relay engineers.

G. W. McKenna: The description by Dr. Gross of the scheme similar to that of Figure 8(B) in the paper, which was used in Europe many years ago, is very interesting and serves to emphasize the author's basic point that with a thorough familiarity with the fundamentals of transformer differential protection, the scope of application of differential relays can be widened greatly to include many unusual circuit arrangements.

Differential Relay Sensitivity Adjuster

C. L. HEADLEY
MEMBER AIEE

ONE OF the primary difficulties experienced in the protection of a power transformer is false tripping by the differential relays on magnetizing inrush current. The magnitude of inrush current is considerably greater on transformers of modern design, and the use of these transformers, especially in the larger size, has greatly increased the difficulty in the application of differential relays.

The purpose of this paper is to describe a device that has been developed which will prevent the differential relay from tripping on magnetizing inrush. This device is arranged to desensitize the relay during the magnetizing inrush period, and it can be applied to any percentage restraint type differential relay.

The Percentage Differential Relay

Typical differential relay connections using a percentage restraint differential relay for the protection of a transformer are shown in Figure 1. Current transformers are shown installed in the connections to the windings of the power transformer.

The normal load or fault current through the power transformer windings causes currents I_1 and I_2 to flow as shown in the secondary winding of the current transformers, X and Y. For simplicity, connections for one phase only are indicated, see Figure 1. The current transformers have ratios so that for normal load or fault currents through the power transformer, the secondary currents produced in the two current transformers will be equal in magnitude. In this way, the secondary currents produced by the current transformers will flow in the restraint windings, R_1 and R_2, of the differential relay as indicated by the arrows, and no net current will flow in the operating winding, O, of the relay.

In the event of a phase-to-ground fault in either winding of the power transformer or within the zone protected by the differential relay, the secondary currents of transformers X and Y will no longer be equal. This is indicated in Figure 2 where the fault current I_3 passes through current transformer X and through the fault path to ground; hence it has no counterpart in current transformer Y. The fault current I_3 produced by current transformer X passes through the restraint winding R_1 and operating winding, O, of the differential relay and if of sufficient magnitude will cause the relay to operate. It will be noted that the counterpart of the load current, I_1 and I_2, which is produced by current transformers X and Y flows through the restraint windings only of the differential relay.

It is highly desirable to have the differential relay operate on a minimum value of fault current in order to detect a fault of low magnitude. For example, if either winding of the transformer illustrated in Figure 2 becomes grounded near the neutral end of the winding, the amount of current which will flow in the fault will be relatively low because of the low voltage to ground. Such a fault should be cleared as quickly as possible to minimize damage and prevent the fault from becoming worse. It is therefore desirable to make the differential relay operate on fault currents of extremely low magnitude in order to obtain the best protection. It is possible to set a percentage differential relay to operate on a relatively low fault current without danger of the relay operating incorrectly because of slight inaccuracies in the current transformers or slight differences from the ratio of the power transformers. However, there is one difficulty that must be considered when applying differential relaying to a power transformer. This difficulty arises from false tripping on magnetizing inrush current experienced when energizing the transformer. A number of methods have been resorted to in order to overcome this trouble. One of these is to set the relay to operate above the inrush current value. Another method is to adjust the time setting so the relay will function only after a relatively long time (1/2 to 1 second). Still another method is a combination in which the differential relay is given a relatively high current setting and a moderately long time setting. Use of any of these methods results in reduced protection to the transformer. Even with the combination method, overcurrent setting may be above full load rating of the transformers and the minimum time setting required would possibly be about 1/2 second. With relay settings such as these, false operation due to magnetizing inrush currents may be avoided but faults of low magnitude would not be detected and when the fault is of sufficient magnitude to be detected, the time in which the relay will operate is longer than desirable.

Differential Relay Sensitivity Adjuster

The difficulties enumerated previously have led to the development of a differential relay sensitivity adjuster of special design which may be connected externally to existing differential relay installations or may be made an integral part of the relay by the manufacturer. The device functions only during periods when the transformer is being energized, and automatically changes sensitivity of the differential relay during that interval to prevent tripping of the circuit breaker on transformer inrush current. This device is shown schematically in Figure 3. It consists of a small reactor, the magnetizing winding of which has a center tap. The ends of this winding are connected to the terminals 1 and 2 of the differential relay to which the restraint coils are con-

Paper 50-190, recommended by the AIEE Relays Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 5, 1950; made available for printing August 9, 1950.

C. L. HEADLEY is with the Consolidated Gas, Electric Light, and Power Company of Baltimore, Baltimore, Md.

Figure 1 (left). Percentage differential relay connections to one phase of a transformer

Figure 2 (right). Percentage differential relay operation on faulted transformer

nected. The center tap of the reactor winding is connected to terminal 3 of the differential relay. The circuit between terminal 3 and the reactor mid-point includes a resistor, R, and contacts, C^1, of a time delay relay, C. Terminal 3 of the differential relay is connected to the common connection of current transformers X and Y.

This reactor provides the main control on the amount of desensitization, the adjustable resistor, R, being provided for making finer adjustments if required. The resistor may be eliminated entirely if the reactor is designed for the particular application or if taps for making adjustments are provided at each end of the reactor.

Relay C shown in Figure 3 is energized through a potential transformer connected to one side of the power transformer which is to be protected. When the relay is de-energized, it closes contacts C^1 immediately. However, upon being energized, the relay opens contacts C^1 after a predetermined time delay.

To illustrate the operation of the sensitivity adjuster, we will assume the power transformer to be de-energized and both the oil circuit breakers X and Y open. With this condition, relay C will be de-energized and contacts C^1 will be closed, connecting the center point of the sensitivity adjuster reactor winding through resistance R to the common connection of the current transformers.

Assume that the power transformer is energized by closing oil circuit breaker X and that an inrush current transient occurs which produces a differential current of large magnitude, I_T, between transformers X and Y in the secondary circuit. This differential current may be considered to flow to terminal 1 of the differential relay. At that point, a portion I_a will flow to terminal 1 of the sensitivity adjuster, through one half of the sensitivity adjuster winding to the center tap, through resistance R, through contacts C^1 and back to the common polarity of current transformer X. The other portion I_b of the differential current will flow from terminal 1 of the differential relay, through restraint winding R_1, to the center tap of the relay, where a portion I_c of this current will flow through the operating winding of the relay to terminal 3, and from there to the common polarity of current transformer X. The remaining portion of the differential current, I_d, will flow from the midpoint of the differential relay, through restraint coil R_2, to terminal 2 of the sensitivity adjuster, through the other half of the sensitivity adjuster winding to the center tap, through resistance R, contact C^1, and from there to common polarity of current transformer X.

It will be noted that the currents I_a and I_d flowing from terminals 1 and 2 respectively, of the sensitivity adjuster flow through each half of the reactor winding to the center tap in opposite directions. In this way, the reactance of the coil is neutralized which permits this portion of the current to be shunted around the operating winding of the differential relay, thus desensitizing the relay operation.

The amount of desensitization of the relay is determined by the value of resistance R which is selected to prevent the relay from operating on magnetizing inrush current.

When the power transformer is energized, relay C is also energized and after a time delay, opens its contacts C^1 to disconnect the center tap of the sensitivity adjuster from the differential relay circuit. With contacts C^1 open, current can flow in the adjuster only through the full reactor winding which now has high impedance as compared to the restraint coils R_1 and R_2 of the differential relay so that the sensitivity adjuster no longer affects the operation of the relay. Therefore, opening of contacts C^1 restores the differential relay to normal sensitivity.

If a fault of sufficient magnitude develops during the short period when the auxiliary contacts C^1 are closed, the current I_c in the operating winding of the relay as previously referred to will be increased sufficiently to cause the differential relay to operate to clear the transformer from the system. However, if the fault is not severe enough to cause the differential relay to operate, the transformer will be cleared when the relay contacts C^1 open. The time required to keep the relay contacts closed depends upon the maximum time duration of the magnetizing inrush current; usually 1/2 to 2 seconds is sufficient.

Several different methods of closing contacts C^1 have been used and have proven satisfactory. These methods include response to absence of potential on the power transformer, use of an auxiliary switch on the transformer circuit breakers, and energizing the relay from the closing circuit of the transformer circuit breakers.

The application of the desensitizing circuit to the differential relay has the advantage that the same desensitization is provided regardless of which side of

Figure 3. Percentage differential relay equipped with sensitivity adjuster

Table I. Tests without Sensitivity Adjuster

Test Number	Magnetizing Inrush 33-Kv Amperes—RMS Phase A	Phase B	Phase C	Relay Response
1	700	1,160	360	Phase B
2	1,200	500	500	Phase A
3	1,300	1,200	700	Phase A and Phase B

the transformer is energized initially. A further advantage in these arrangements is that the desensitizer may be applied externally to the differential relay and does not require circuit changes within the relay. It also permits setting the relay for maximum sensitivity under normal operating conditions.

In 3-phase applications, one sensitivity adjuster is required for each phase element of the differential relay. The center tap of the reactor winding of each adjuster is connected in series with a resistor and through a pair of contacts on the time delay relay to the operating coil terminal of each differential relay. The outside reactor terminals 1 and 2 are connected to the restraint coil terminals of each differential relay. With the sensitivity adjuster connected as described, no change is made in the differential relay adjustment, nor is the operation of the relay affected so long as the relay contacts C^1 remain open. However, during the interval when the power transformer is being energized, the contacts C^1 are closed to effect desensitizing the differential relay to prevent tripping on magnetizing inrush current.

Performance

The following tests were made by energizing a General Electric 40,000-kva 33/110-kv 3-phase transformer at the Riverside Station of the Consolidated Gas, Electric Light, and Power Company of Baltimore. The transformer was protected by a General Electric type *IJD* differential relay.

Table II. Tests with Sensitivity Adjuster Connected

Test Number	Magnetizing Inrush 33-Kv Amperes—RMS Phase A	Phase B	Phase C	Relay Response
4	350	340	860	None
5	400	1,140	620	None
6	1,200	540	1,200	None
7	700	1,160	400	None
8	1,150	500	400	None

The differential relay was adjusted for the test to operate at approximately 400 amperes at 33 kv with a minimum time for operation of approximately 0.1 second.

The sensitivity adjuster was set to reduce the sensitivity of the differential relay during the magnetizing inrush period from 400 amperes to approximately 1,100 amperes at 33 kv.

The tests were made by energizing the transformer from the 33-kv bus by closing the oil circuit breaker. Tables I and II give the test results with and without the sensitivity adjuster.

Discussion

Eric T. B. Gross (Illinois Institute of Technology, Chicago, Ill.): It appears that the main difficulty experienced with differential protection has been false tripping on transient components of magnetizing currents. Larger inrush currents are being observed on transformers of modern design, not only upon energizing by switching in, but also after through faults upon switching off of the remote short circuit by the circuit breaker next to it. Many solutions have been suggested,[1–4] but the problem of eliminating false tripping of differential relays still seems to exist. I am wondering if the author would show how the sensitivity adjuster described in this paper would eliminate without exceptions false tripping because of magnetizing current transients after through faults, when there was no operation of the transformer circuit breakers, but only of a remote circuit breaker near the far away fault or near a fault in the section next to the transformer installation.

It seems to me that we are still short of a step forward in the direction to higher sensitivity of transformer protection. Surely, we have learned to build better transformers, but we also use larger transformers, and increased sensitivity of protection means reduced damage, and faster and cheaper repair in those few cases of transformer failure that remain. Many kinds of faults are possible, within the tank of transformers, which produce unbalances that are smaller than the permissible lowest setting of any type of differential relay. It may be pointed out that gas and pressure relays provide a solution with greatly increased sensitivity, and without all the troubles produced by inrush currents. Perhaps it is worthwhile to cite here the recommendations of the latest AIEE Committee Report[5] on Transformer Protection which states:

"The value of gas accumulator relays for detecting incipient faults has been underestimated generally in the United States.

"1. Substantial experience in Canada has demonstrated the value of gas accumulator relays to detect conditions such as turn-to-turn faults, core insulation failures, and defective joints.

"2. Objections commonly raised to the gas accumulator method of detecting faults can be overcome largely by suitable application and proper interpretation of relay indications.

"3. The present commercially developed gas detector relays are limited in application to conservator-type transformers. Experimental installations indicate that devices may be developed for extending gas detection principles to other types of transformers.....

"The wider application of pressure protection offers considerable promise. (1) To provide supplemental protection with sensitivity greater than usually obtained with conventional differential schemes alone. (2) For protection, when used with overcurrent relays, where it is not feasible to provide a satisfactory differential scheme. (3) To solve inherently difficult application problems, such as with step regulators and rectifier transformers. (4) For fast low-cost protection and reclosing lockout of feeder voltage regulators."

C. L. Headley: In his discussion, Mr. Gross has pointed out that magnetizing inrush currents may be experienced in a transformer immediately following a fault through the transformer that is cleared by a remote circuit breaker, that is, on the secondary side of the transformer. Such a fault would leave the transformer in service. Mr. Gross has asked if the sensitivity adjuster as described will prevent the differential relay from tripping the transformer circuit breaker on this type of magnetizing current transient.

We have never experienced incorrect tripping by the differential relay on magnetizing inrush following a fault current through the transformer. However, the transformer differential relay sensitivity adjuster as described in the paper is controlled by a potential relay which is energized from one side of the transformer that is being protected. Upon being energized, normally closed contacts of the potential relay open after a predetermined time delay to restore the differential to its normal sensitivity. But, upon being de-energized, the potential relay immediately closes its contacts which desensitize the differential relay.

With this arrangement and proper setting of the potential relay to close on reduced voltage, a fault current through the transformer of sufficient magnitude to cause an inrush current great enough to operate the differential relay, will also cause a sufficient drop in voltage at the terminals of the transformer to close the potential relay contacts. This activates the sensitivity adjuster applied to the differential relay circuit and prevents the relay from tripping on the magnetizing inrush transient.

Of course, if the transformer carries load immediately following the clearing of a fault, the load current through the transformer helps to prevent the differential relay from tripping by action of the restraint windings in the relay. Also, the load through the transformer helps to reduce the inrush transient time.

Gas and pressure relays offer a solution for the protection of transformers on faults of low magnitude, particularly on turn-to-turn faults. Also, they are free from troubles produced by inrush currents. However, it is felt that transformers equipped with gas or pressure relays also should be protected by a standard differential relay. One method of protection that we have used successfully where the application of differential relays is difficult, such as induction regulators, step regulators, and phase shifters, is the case ground relay. Such relays are comparatively easy to apply and they can be set with sufficient sensitivity to detect phase-to-case faults of extremely low magnitude. We have experienced several operations of this type of relaying and in each case the trouble was cleared without disturbance to the system and relatively small damage to the equipment.

Resistance Commutation

FRANK D. OLNEY
MEMBER AIEE

Synopsis: Thorburn Reid considered the commutation problem in rotating machines as arising from reactance in the coils being commutated by the varying brush contact resistance. This paper extends Reid's treatment to include the effects of reactance in the coils which are not being commutated, and shows that these noncommutating coils are an important factor in commutation performance. An equivalent circuit for a simplified commutator machine is developed and used as the basis for the analysis given in Appendixes I through VI. By means of this equivalent circuit, the average brush terminal voltage is seen to approach the value of the commutating reactance voltage under severe commutating conditions. Voltage pulses near the end of the commutation period are shown to be produced by a parallel influence of the noncommutating and the commutating coils. A testing device based on the equivalent circuit is described in Appendix VI, and consists of a mechanical inverter connected so as to separate the functions of the brushes in reversing current through the commutating coils, and in passing current through the noncommutating coils. When connected to the armature of a particular machine, the testing device is used to measure the commutating reactance and the brush contact resistance under simulated operating conditions. By means of this device, a correlation between brush electrical wear and severity of commutating conditions is established, which helps to confirm the basic theory.

THE MANY important military, industrial, and domestic applications of commutator machines make it necessary that designers know the commutating ability of these machines. Where commutating poles are used within their range of effectiveness, commutation performance can be predicted with reasonable accuracy. However, where the varying resistances of the brush-to-segment contacts are depended upon to control the commutation, that is, resistance commutation, there is a need for fundamental design information on which may be based calculations of commutation performance from circuit data.

Thorburn Reid[1,2] showed that high voltages appear across the brush-to-segment contact when there is a large reactance in the coils being commutated by the varying brush contact resistance. In a machine connected to a constant line voltage, however, these high voltages can occur only if there is an additional impedance in the circuit across which an opposing voltage may be developed. The present paper shows that the noncommutating coils provide this additional impedance.

The machine selected for analysis is operated from a constant voltage line, and has symmetrical windings in which commutation is accomplished in the neutral zone by means of brushes which span one commutator segment. The magnetic field in the air gap due to armature reaction is considered to be fully compensated. The machine speed is constant, so that the generated voltage due to field excitation of the noncommutating coils and its counterpart in the external line voltage may be omitted. That is, the only external line voltage considered will be that component required to overcome the brush terminal voltage.

The only assumption required under these conditions is that concerning the brush-to-bar contact. Mechanically perfect bearings, commutator, brushes and brushholders are assumed so that electrical contact between the brush and segment is continuous. The contact resistance is assumed to vary inversely with the contact area and to be independent of instantaneous current density under transient conditions. The transient conditions considered are those occurring during the usual commutation period with a duration of the order of one millisecond. No assumption is required as to the condition of the contact film, since the method of analysis utilizes the per-unit system to take into account any relatively slow variations of the film and thus of the contact resistance such as occur with changes in average line current, temperature, wear, atmosphere, and other commutating conditions. This use of the per-unit system, or dimensionless grouping, also will allow test results to be duplicated even though the commutator film changes as a result of load change.

Analysis

Faraday's experiments showed that induced voltages are proportional to the rate of change of flux linkages with the circuit, so that a continuous voltage cannot be induced in an uninterrupted circuit unless the flux increases indefinitely. Therefore, an essential part of every d-c machine, in addition to a provision for generating a voltage, is a means for reducing the flux linkages at intervals by a substitution of circuit[3] in an attempt to avoid generating a voltage, as may be done by the use of a commutator. A commutator may be thought of as a mechanical switch connecting individual armature coils to the power line in such a manner that as a coil is disconnected from the power line, it is short-circuited by the brushes, the polarity is reversed, and it is reconnected to the power line. Complication arises from the fact that the disconnection, short circuit, reversal, and reconnection proceed simultaneously. This complication, together with the fact that outside the range of effectiveness of commutating poles and in all but acyclic machines, the reduction of flux linkages at intervals by a substitution of circuit actually does generate a voltage which appears at the machine terminals, and the additional fact that the brushes are at the same time passing current through the reactance of the remainder of the armature, has led to various opinions as to the

Paper 50-191, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted March 8, 1950; made available for printing July 31, 1950.

FRANK D. OLNEY is with the General Electric Company, Fort Wayne, Ind.

Figure 1 (left). Schematic diagram of commutator machine

Figure 2 (right). Equivalent circuit of commutator machine

particular factors which give rise to the commutation problem.

The method of analysis used in this paper is to set up an equivalent circuit for a simplified machine as would be seen from reference axes fixed with respect to the commutating coils, to make calculations of commutation performance based on this circuit as given in Appendixes I through V, and then to check the calculations using a test device in which each element entering into the commutation problem may be separately evaluated by suppressing the effects of other elements, as described in Appendix VI. In this way, the basic theory of commutation may be established on a firm footing before some of the more complicated factors met in machines are considered.

Figure 1 is a schematic view of a simplified machine which contains the essential features of more complicated machines. Only two poles and four slots are shown, but of course the analysis is equally valid for any number of slots or poles. The coils in the slots marked (a) are the noncommutating coils, and the edges of the brushes marked (1) are the trailing edges. The commutator bars in contact with the trailing edges of the brushes are termed the trailing bars.

If each brush is separated into leading and trailing contacts, with the insulation between bars as the dividing line, to an observer moving with the armature the circuit of Figure 2 is electrically equivalent to that of Figure 1. The reference axes are fixed in the armature since it is possible for flux to reverse with respect to an armature coil and yet be unchanged with respect to the field, because of rotation. Neukirchen[4] has shown that over 98 per cent of the total brush resistance is in the commutator-to-brush contact and less than 2 per cent is in the brush body of usual brushes, so that the assumed resistance of the trailing contact becomes

$$R_1 = \frac{R}{1-t} \text{ ohms} \tag{1}$$

and the resistance of the leading contact is

$$R_2 = \frac{R}{t} \text{ ohms} \tag{2}$$

Direct analysis of the circuit in Figure 2 is possible, but some of the equations will be redundant because of the symmetry of the circuit. The same voltage will appear across each of the two commutating coils so that they may be combined, but the inductance coefficients should be halved to compensate for the doubling of the current in the combined coils. If this is done, a similar combination of the noncommutating coils will then result in the simplified equivalent circuit of Figure 3.

The simplified equivalent circuit contains the essential geometry of the machine as far as commutation is concerned, and has the general form of a bridge circuit in which the commutating coil carries the unbalance current. Since the arms of the bridge are composed of contact resistances which vary with time, it is possible that the bridge circuit in the path of the line current will act as an impedance which is greater than the net ohmic value of the contact resistances in cases where the commutating inductance is large.

A physical picture of the mechanism by which current is reversed in the commutating coil may be obtained by observing the current paths in the simplified equivalent circuit at the start, mid-point, and end of the commutation period. At the start of the commutation period, the leading contact resistance is open-circuited and the trailing contact resistance is a minimum, so that the line current path is as shown in Figure 4. The brush terminal voltage tends to increase the line current above its initial value, but this increase is opposed by the voltage developed by the reactance of the coils.

At the mid-point of the commutation period, the contact resistances are equal so that the line current divides as it enters the armature, as shown in Figure 5. The current through the commutating coil will be determined by circuit conditions and so is shown dotted.

At the end of the commutation period, the leading contact resistance is a minimum and the trailing contact resistance is open-circuited, so that the line current path is as shown in Figure 6. If the current in the commutating coil has not sufficiently reversed before this time, it can be seen that the line current will be opposed, and that a high voltage may be developed across the noncommutating coils in an attempt to maintain the line current. Commutation is a repeated transient, so that the line current at the end of the period must be the same as at the start of the period. This restriction on the line current gives the boundary conditions to be applied in the analysis, since this means that the commutating coil current must exactly reverse by the end of the period. However, this does not mean that the line current must be constant throughout the commutation period, nor does it place restrictions on the rate of change of line current, nor does it mean that the initial value of the commutating coil current must be equal to the average value of the line current.

Kirchhoff's equations for the circuit of Figure 3 are, where the elapsed time in seconds is written as tT so as to simplify the form of the solutions

$$\frac{L_a}{2T}\frac{d}{dt}(i_1+i_3)+R_1i_1+R_2i_3=e \tag{3}$$

$$i_1=i_2+i_3 \tag{4}$$

$$\frac{L}{2T}\frac{di_3}{dt}+R_1i_1-R_2i_3=0 \tag{5}$$

Figure 3. Simplified equivalent circuit

Figure 4. Current path at start of commutation period

Solutions to these equations are given in the appendixes as follows:

Appendix	Ratio of Noncommutating to Commutating Inductance
I	Zero
II	Unity
III	Greater than unity (general case)
IV	Extremely large
V	Zero, but with line resistance

Typical Results

Figure 7 gives the calculated brush terminal voltage for particular values of the commutating and noncommutating inductances, together with test points taken by means of the device described in Appendix VI. The per-unit brush terminal voltage is an index to the severity of the commutating conditions, and has important effects on the short-circuit current of d-c generators, on the sensitivity of amplidynes, on the brush and commutator temperature, and so on. It should be noted that the curves shown are not affected by brush grade, brush temperature, brush spring pressure, type of commutator, speed, average line current, surface film, and so forth, as long as the assumptions are not violated.

Figures 8 and 9 give values for the commutating coil current and line current during the commutation period for typical circuit conditions. The effect of commutating and noncommutating reactance on the line current ripple is shown in Figure 10. The typical saw-tooth shape of the line current is seen to be a result of commutation, and not a result of air-gap permeance variations caused by slots. The significance of line current ripple is that the average commutating coil voltage depends only on the initial line current and is not exactly proportional to the average line current if the brush contact resistance varies with line current, atmosphere, temperature, brush grade, and so forth. Although outside the scope of this paper, this nonlinearity has application to the shape of the black band on certain machines when commutating poles are used, and indicates the reason why a slightly stronger commutating pole field may be needed if low-resistance brushes are replaced by high-resistance brushes.

Figure 5. Current paths at mid-point of commutation period

Figures 11, 12, 13, and 14 give values for the circuit voltages during the commutation period for typical commutating conditions. The production of pulse voltages near the end of the commutation period under severe commutating conditions can be seen from these curves. The effect of these pulses on the brushes and bars may be appreciated when it is realized that the square of the trailing brush contact voltage gives the watts per square inch over the trailing contact area, under the assumption that contact resistance is inversely proportional to contact area. That is, if the trailing contact voltage pulse reaches ten times the normal brush drop, the dissipated power density reaches 100 times normal. The effect of the pulses across the noncommutating coils has application to the flashover problem of commutators. In practice, of course, the assumptions made concerning the contact resistance will not hold for the extremely small time interval during which the high-voltage pulse is applied, and this, together with the interturn capacitance, will limit the peak value of the pulse.

Figure 15 is included as an aid to the analysis of Appendix III, and shows average values of the leading brush contact voltage plotted as a ratio to the final leading brush drop instead of in per unit of the base voltage.

Nomenclature

e = Brush terminal voltage for the positive plus the negative brushes
E = Line voltage (appendix V)
I = Average line current, amperes
I_0 = Line current at start or end of commutation period, amperes
i_1 = Trailing brush contact instantaneous current, amperes
i_4 = Leading brush contact instantaneous current, amperes
i_4 = Commutating coil instantaneous current, amperes
L = Commutating coil differential[13] inductance, henrys. This is one-half the sum of the self and mutual inductances of all coils simultaneously commutated by one pair of brushes of opposite polarity

Figure 6. Current path at end of commutation period

L_a = Noncommutating coil differential[13] inductance for one armature circuit, including mutual inductance with other armature circuits, henrys.
R = Brush contact resistance for one full contact area, ohms
R_1 = Trailing brush contact instantaneous resistance, as a function of the trailing contact area, ohms
R_4 = Leading brush contact instantaneous resistance, as a function of the leading contact area, ohms
r = Line resistance, ohms (appendix V)
t = Elapsed time in per unit of commutation period. (t ranges from 0 to 1).
T = Commutation period or time for trailing brush to go from full to zero contact area with respect to one segment, seconds (T is inversely proportional to the speed of rotation)

$$s = \mathrm{Tanh}^{-1}\frac{(1-2t)}{\sqrt{1+\frac{2R}{r}}} \text{ (appendix V)}$$

Per-Unit System[5]

Base Quantities

Unit time = T seconds
Unit resistance = 2 R ohms (positive plus negative brush)
Unit current = I amperes
Unit voltage = (unit ohms) (unit amperes) = 2 IR
Unit inductance = (unit ohms) (unit time) = 2 RT henrys
Unit brush life is explained in Appendix VI

Some Per-Unit Quantities

Per-unit time = t
Per-unit brush terminal voltage = $e/2\,IR$
Per-unit initial line current (line current ripple) = I_0/I
Per-unit reactance voltage = $L/2\,RT$ (in a strict sense, this is the per-unit commutating inductance, but by multiplying numerator and denominator by the average line current, it becomes per-unit reactance voltage, if there is no line current ripple)

Appendix I. Noncommutating Inductance Equal to Zero

Cases in which there is no noncommutating inductance are not ordinarily met in practice, but the analysis is presented be-

Figure 7 (left). Per-unit brush terminal voltage

Figure 9 (right). Per-unit line current

cause it completes the range of circuit constants and affords a physical understanding of the commutation process.

If currents i_1 and i_2 are eliminated in equations 3, 4, and 5, there results an equation containing the commutating coil current, when $I_a=0$

$$\frac{L}{2T}\frac{di_3}{dt}+\frac{2R_1R_3}{R_1+R_3}i_3+\frac{R_1-R_3}{R_1+R_3}e=0 \qquad (6)$$

Putting the assumed contact resistances from equations 1 and 2 into 6

$$\frac{L}{2T}\frac{di_3}{dt}+2Ri_3=(1-2t)e \qquad (7)$$

Equation 7 is linear and indicates that with respect to the armature, the commutation circuit contains an applied brush terminal voltage which linearly reverses during the commutation period. The solution to equation 7 is, after the boundary condition that at $t=0$, $i_3=I_0$ is applied

$$\frac{i_3}{I_0}=\epsilon^{-\frac{4RT}{L}t}+\frac{e}{2I_0R}\times\left[\left(1+\frac{L}{2RT}\right)\left(1-\epsilon^{-\frac{4RT}{L}t}\right)-2t\right] \qquad (8)$$

It can be seen from Figure 8 that during the first half of the commutation period the commutating coil current increases rather than decreases, in the absence of any noncommutating inductance. The commutating coil current must reverse by the end of the commutation period, so applying the boundary condition that at $t=1$, $i_3=-I_0$, the value of the brush terminal voltage is

$$\frac{e}{2I_0R}=\frac{1+\epsilon^{-\frac{4RT}{L}}}{2-\left(1+\frac{L}{2RT}\right)\left(1-\epsilon^{-\frac{4RT}{L}}\right)} \qquad (9)$$

The line current is found by substituting the commutating coil current from equation 8 into equations 3 and 4

$$\frac{i_1+i_2}{I_0}=(1-2t)\epsilon^{-\frac{4RT}{L}t}+\frac{e}{2I_0R}\times\left[\left(1+\frac{L}{2RT}\right)(1-2t)\left(1-\epsilon^{-\frac{4RT}{L}t}\right)+2t\right] \qquad (10)$$

When the line current is averaged over a commutation period, the voltages and currents may be plotted in terms of the average line current instead of the initial line current. However, the expressions for voltage and current as explicit functions containing the average line current are complicated, and so the form used in equations 8, 9, and 10 in terms of the initial line current will be continued through the remainder of the mathematical analysis.

The trailing brush contact current is found from equations 3, 4, and 8 as

$$\frac{i_1}{I_0}=(1-t)\epsilon^{-\frac{4RT}{L}t}+\frac{e}{2I_0R}\left(1+\frac{L}{2RT}\right)\left(1-\epsilon^{-\frac{4RT}{L}t}\right)(1-t) \qquad (11)$$

and similarly, the leading brush contact current is

$$\frac{i_2}{I_0}=\frac{e}{I_0R}t-t\epsilon^{-\frac{4RT}{L}t}-\frac{e}{2I_0R}\left(1+\frac{L}{2RT}\right)\left(1-\epsilon^{-\frac{4RT}{L}t}\right) \qquad (12)$$

The remainder of the circuit quantities can be determined directly from equations 1 through 5 without differentiation or integration, and typical values are shown in Figures 11 through 14.

Appendix II. Noncommutating Inductance Equal to Commutating Inductance

For the special case where the noncommutating inductance is equal to the commutating inductance, equations 3, 4, and 5

Figure 8 (left). Per-unit commutating coil current

Figure 10 (right). Per-unit initial line current

Figure 11 (left). Per-unit commutating coil voltage

Figure 13 (right). Per-unit trailing brush contact voltage

are solved by eliminating the commutating coil current. If this is done, there results

$$\frac{L}{T}\frac{di_1}{dt}+2R_1i_1=e \tag{13}$$

$$\frac{L}{T}\frac{di_2}{dt}+2R_2i_2=e \tag{14}$$

Putting the assumed contact resistances from equations 1 and 2 into equations 13 and 14 yields

$$\frac{L}{T}\frac{di_1}{dt}+\frac{2R}{1-t}i_1=e \tag{15}$$

$$\frac{L}{T}\frac{di_2}{dt}+\frac{2R}{t}i_2=e \tag{16}$$

The solutions to equations 15 and 16 are, after the initial boundary condition is applied that at $t=0$, $i_1=I_0$, and $i_2=0$.

$$\frac{i_1}{I_0}=(1-t)^{\frac{2RT}{L}}+\frac{e}{2I_0R}\left(\frac{1}{1-\frac{L}{2RT}}\right)\times\left(1-t-(1-t)^{\frac{2RT}{L}}\right) \tag{17}$$

$$\frac{i_2}{I_0}=\frac{e}{2I_0R}\left(\frac{t}{1+\frac{L}{2RT}}\right) \tag{18}$$

Then from equation 4, the commutating coil current is

$$\frac{i_3}{I_0}=(1-t)^{\frac{2RT}{L}}+\frac{e}{2I_0R}\times\left[\frac{1-(1-t)^{\frac{2RT}{L}}}{1-\frac{L}{2RT}}-\frac{2t}{1-\left(\frac{L}{2RT}\right)^2}\right] \tag{19}$$

In order to meet the final boundary condition that at $t=1$, $i_3=-I_0$, the brush terminal voltage becomes

$$\frac{e}{2I_0R}=1+\frac{L}{2RT} \tag{20}$$

The line current is, from equations 17 and 18

$$\frac{i_1+i_2}{I_0}=(1-t)^{\frac{2RT}{L}}+\frac{e}{2I_0R}\times\left[\frac{1-(1-t)^{\frac{2RT}{L}}}{1-\frac{L}{2RT}}-\frac{\frac{L}{RT}}{1-\left(\frac{L}{2RT}\right)^2}t\right] \tag{21}$$

When this line current is averaged over a commutation period as shown in Figure 10, the voltages and currents may be expressed in the per-unit system.

At a value of the per-unit reactance voltage equal to unity, equation 17 for the trailing brush current becomes indeterminate, so that for this point only

$$\left.\frac{i_1}{I_0}\right|_{\frac{L}{2RT}=1}=(1-t)\left[1-\frac{e}{2I_0R}\log(1-t)\right] \tag{22}$$

The remaining circuit quantities may be determined directly from equations 1 through 5, and typical values are given in Figures 11 through 14.

Appendix III. Noncommutating Inductance Greater than Commutating Inductance (General Case)

In general, the noncommutating inductance is larger than the commutating inductance in practical machines. For this case, equations 1 through 5 will be solved by approximating that variations of the leading contact voltage drop from its average value have no effect on the commutation performance. The error due to this approximation can be determined readily, and will be shown to be negligible. Physically, this approximation is equivalent to considering that resistance commutation consists largely in the interruption of current in an inductive circuit by means of contacts in which the contact area decreases at a constant rate.

When the commutating coil current is eliminated in equations 3, 4, and 5, there results

$$\frac{L_s}{2T}\frac{d}{dt}(i_1+i_2)+R_1i_1+R_2i_2=e \tag{23}$$

$$\frac{L}{2T}\frac{d}{dt}(i_1-i_2)+R_1i_1-R_2i_2=0 \tag{24}$$

Multiplying equation 23 by L/L_s

Figure 12 (left). Per-unit noncommutating coil voltage

Figure 14 (right). Per-unit leading brush contact voltage

Figure 15. Average leading brush contact voltage

$$\frac{\bar{L}}{2T}\frac{d}{dt}(i_1+i_2)+\frac{\bar{L}}{L_a}R_1i_1+\frac{\bar{L}}{L_a}R_2i_2=\frac{\bar{L}}{L_a}e \qquad (25)$$

and adding equations 24 and 25

$$\frac{L}{T}\frac{di_1}{dt}+\left(1+\frac{L}{L_a}\right)R_1i_1 = \frac{L}{L_a}e+\left(1-\frac{L}{L_a}\right)R_2i_2 \qquad (26)$$

If the leading contact is considered to introduce only a constant voltage, written as $(R_2i_2|\text{av})$, then equation 26 becomes, using equation 1

$$\frac{L}{T}\frac{di_1}{dt}+\left(1+\frac{L}{L_a}\right)\left(\frac{R}{1-t}\right)i_1 = \frac{L}{L_a}e+\left(1-\frac{L}{L_a}\right)(R_2i_2|\text{av}) \qquad (27)$$

The solution to equation 27 is, after the boundary conditions are applied that at $t=0$, $i_1=I_0$, and at $t=1$, $i_1=0$

$$\frac{i_1}{I_0}=\left[1-\frac{\frac{L}{L_a}\left(\frac{e}{I_0R}\right)+\left(1-\frac{L}{L_a}\right)\left(\frac{R_2i_2|\text{av}}{I_0R}\right)}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]\times (1-t)^{\left(1+\frac{L}{L_a}\right)\frac{RT}{L}}+\left[\frac{\frac{L}{L_a}\left(\frac{e}{I_0R}\right)+\left(1-\frac{L}{L_a}\right)\left(\frac{R_2i_2|\text{av}}{I_0R}\right)}{1+\frac{L}{L_a}-\frac{L}{RT}}\right](1-t) \qquad (28)$$

Equation 28 compares exactly with equation 17 in Appendix II for the case where $L_a=L$.

Subtracting equation 24 from 25

$$\frac{L}{T}\frac{di_2}{dt}+\left(\frac{L}{L_a}-1\right)R_1i_1=\frac{L}{L_a}e-\left(1+\frac{L}{L_a}\right)R_2i_2 \qquad (29)$$

and again considering only the average value of the leading contact drop, and using equation 1

$$\frac{L}{T}\frac{di_2}{dt}+\left(\frac{L}{L_a}-1\right)\left(\frac{R}{1-t}\right)i_1=\frac{L}{L_a}e-\left(1+\frac{L}{L_a}\right)(R_2i_2|\text{av}) \qquad (30)$$

The value of trailing contact current found in equation 28 is substituted into equation 30, so that

$$\frac{L}{T}\frac{di_2}{dt}+I_0R\left(\frac{L}{L_a}-1\right)\times\left[1-\frac{\frac{L}{L_a}\left(\frac{e}{I_0R}\right)+\left(1-\frac{L}{L_a}\right)\left(\frac{R_2i_2|\text{av}}{I_0R}\right)}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]\times (1-t)^{\left(1+\frac{L}{L_a}\right)\frac{RT}{L}-1}+I_0R\left(\frac{L}{L_a}-1\right)\times\left[\frac{\frac{L}{L_a}\left(\frac{e}{I_0R}\right)+\left(1-\frac{L}{L_a}\right)\left(\frac{R_2i_2|\text{av}}{I_0R}\right)}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]=\frac{L}{L_a}e-\left(1+\frac{L}{L_a}\right)(R_2i_2|\text{av}) \qquad (31)$$

The solution to equation 31 is, after the boundary conditions are applied that at $t=0$, $i_2=0$, and at $t=1$, $i_2=I_0$

$$\frac{i_2}{I_0}=\left(\frac{L}{L_a}-1\right)\left[\frac{1-\left(\frac{R_2i_2|\text{av}}{I_0R}\right)-\frac{L}{RT}}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]\times\left[(1-t)^{\left(1+\frac{L}{L_a}\right)\frac{RT}{L}}-(1-t)\right]+t \qquad (32)$$

where the brush terminal voltage must satisfy the relation

$$e=\frac{I_0L}{T}+2(R_2i_2|\text{av}) \qquad (33)$$

Equation 33 can be seen by inspection of the equivalent circuit in Figure 3, since physically this states that the brush terminal voltage is equal to the sum of the reactance voltage and twice the average of the leading brush contact voltage drop, if line current ripple is negligible.

Substituting the brush terminal voltage from equation 33 into equation 28, the trailing brush contact current becomes

$$\frac{i_1}{I_0}=\left(1+\frac{L}{L_a}\right)\left[\frac{1-\left(\frac{R_2i_2|\text{av}}{I_0R}\right)-\frac{L}{RT}}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]\times (1-t)^{\left(1+\frac{L}{L_a}\right)\frac{RT}{L}}+\left[\frac{\frac{L}{L_a}\left(\frac{L}{RT}\right)+\left(1+\frac{L}{L_a}\right)\left(\frac{R_2i_2|\text{av}}{I_0R}\right)}{1+\frac{L}{L_a}-\frac{L}{RT}}\right]\times(1-t) \qquad (34)$$

The remaining step in the analysis is to determine the average leading contact drop. Averaging, over a commutation period, the product of the leading contact current from equation 32 and the leading contact resistance from equation 2, there results for the special case where $L/2RT=1+L/L_a$

$$\left.\frac{R_2i_2}{I_0R}\right|_{\text{av}}^{\frac{L}{2RT}=1+\frac{L}{L_a}}=\frac{1-\left(\frac{1-\frac{L}{L_a}}{1+\frac{L}{L_a}}\right)\left(1+2\frac{L}{L_a}\right)(\log 4-1)}{1+\left(\frac{1-\frac{L}{L_a}}{1+\frac{L}{L_a}}\right)(\log 4-1)} \qquad (35)$$

Values of the average leading contact voltage from equation 35, together with values obtained by numerical integration, are plotted in Figure 15. These values enable the commutation performance to be determined from equations 4, 23, 24, 32, and 34 without differentiation or integration. Typical cases are shown in Figures 7–14.

An explicit expression for line current ripple is found by averaging the sum of the leading and trailing brush contact currents from equations 32 and 34

$$\frac{I}{I_0}=\int_0^1\frac{(i_1+i_2)}{I_0}dt=1+\frac{L}{L_a}\left(\frac{\frac{L}{RT}+\frac{R_2i_2|\text{av}}{I_0R}-1}{1+\frac{L}{L_a}+\frac{L}{RT}}\right) \qquad (36)$$

Values from equation 36, after inversion, are shown in Figure 10, and these values are used to express the remaining quantities in the per-unit system.

The error involved in the approximation concerning the effect of variations in the leading contact drop can be found by comparison with exact analysis. For the case where $L_a=L$, equations 32 and 34 become identical with equations 17 and 18 in Appendix II, so there is no error. For the case where L_a is extremely large, at a per-unit reactance voltage equal to 1, the approximate brush terminal voltage is within 2 per cent of the exact value found in Appendix IV. Since these two cases bracket the applicable range of constants, the approximation is considered satisfactory, and the effect on the voltage and current wave shapes is practically negligible.

The parallel influence of the commutating and noncommutating coils in producing voltage pulses at the end of the commutation period can be seen if equations 1 and 34 are used to express the trailing contact drop. The transition from pulses of low peak value to pulses which approach the shape of the trailing brush contact resistance occurs when the quantity $LL_a/(L+L_a)$ exceeds RT. In excess of this value, the trailing contact voltage becomes asymptotic to the trailing contact resistance.

Appendix IV. Noncommutating Inductance Extremely Large

As the noncommutating inductance becomes extremely large, the line current be-

comes constant so that $I_b = I$ (but the instantaneous rate of change of line current may have any value), and equation 5 becomes

$$\frac{L}{2T}\frac{di_2}{dt} + \frac{R_1}{2}(I+i_2) - \frac{R_2}{2}(I-i_2) = 0 \tag{37}$$

where

$$i_1 = \frac{I+i_2}{2} \tag{38}$$

$$i_2 = \frac{I-i_2}{2} \tag{39}$$

Substituting the assumed contact resistance values from equations 1 and 2 into equation 37

$$\frac{L}{T}\frac{di_2}{dt} + \frac{R(I+i_2)}{1-t} - \frac{R(I-i_2)}{t} = 0 \tag{40}$$

Some special solutions to equation 40 have been presented by Thorburn Reid,[1,9] two examples of which are

$$\left.\frac{i_2}{I}\right|_{\frac{L}{2RT}=\frac{1}{2}} = 2\left(1-\frac{1}{t}\right)\log(1-t) - 1 \tag{41}$$

$$\left.\frac{i_2}{I}\right|_{\frac{L}{2RT}=1} = \sqrt{\frac{1}{t}-1}\,[\cos^{-1}(1-2t)] - 1 \tag{42}$$

From equations 1, 38, and 42 the average value of the trailing brush contact voltage for a per-unit reactance voltage of unity is

$$\left.\frac{R_1 i_1}{IR}\right|_{\text{av}\ \frac{L}{2RT}=1} = \int_0^1 \frac{\cos^{-1}(1-2t)}{2\sqrt{t(1-t)}}\,dt = \frac{\pi^2}{4} = 2.467 \tag{43}$$

From the equivalent circuit of Figure 3 it is seen that

$$e = 2(R_1 i_1|\text{av}) - \frac{IL}{T} \tag{44}$$

from which, by dividing by $2IR$, and using equation 43

$$\left.\frac{e}{2IR}\right|_{\frac{L}{2RT}=1} = \frac{R_1 i_1|\text{av}}{IR} - \frac{L}{2RT} = 2.467 - 1 = 1.467 \tag{45}$$

As a comparison with the approximate case given in Appendix III, if the values $L_a = \infty$ and $L/2RT = 1$ are substituted into equations 33 and 35 for the approximate case

$$\left.\frac{e}{2IR}\right|_{\frac{L}{2RT}=1\ \text{(approx.)}} = \frac{2}{\log 4} = 1.443 \tag{46}$$

which compares with the exact value in equation 45.

The voltage appearing across the noncommutating coils is found from equation 3 as

$$\frac{L_a}{2T}\frac{d}{dt}(i_1+i_2) = e - R_1 i_1 - R_2 i_2 \tag{47}$$

and has the instantaneous values given in Figure 12 even though the line current is constant, since the noncommutating inductance is considered to be extremely large.

It will be noted that an extremely large noncommutating inductance in series with the commutation bridge network corresponds physically to an integrating circuit which produces a terminal voltage nearly equal to the average value of reactance voltage.

Appendix V. Line Resistance in Place of Noncommutating Inductance

The voltage pulses calculated in Appendixes II, III, and IV, are contingent on the presence of noncommutating inductance. The question then arises as to whether or not these pulses are produced if the noncommutating inductance is replaced by line resistance. This has application to generators supplying resistance loads, to dynamic braking of motors, and to simulated commutation testing.[11,12]

If line resistance, r, is used in place of the noncommutating inductance in the equivalent circuit of Figure 3, and line voltage, E, is used in place of the brush terminal voltage, equation 3 becomes

$$r(i_1+i_2) + R_1 i_1 + R_2 i_2 = E \tag{48}$$

where

$$E = e + Ir \tag{49}$$

Equations 4 and 5 are unchanged, so that eliminating i_1 and i_2 in these equations

$$\frac{L}{2T}\frac{di_2}{dt} + \left[\frac{2R_1R_2 + (R_1+R_2)r}{R_1+R_2+2r}\right]i_2 = \left(\frac{R_1-R_2}{R_1+R_2+2r}\right)E \tag{50}$$

Substituting the assumed contact resistances from equations 1 and 2 into 50

$$\frac{L}{2T}\left(1+\frac{2r}{R}t(1-t)\right)\frac{di_2}{dt} + (2R+r)i_2 = (1-2t)E \tag{51}$$

which is a linear equation with variable inductance.

In order to solve equation 51, make the change in variable

$$s = \tanh^{-1}\frac{1-2t}{\sqrt{1+\frac{2R}{r}}} \tag{52}$$

so that equation 51 becomes

$$\frac{L}{2T}\frac{di_2}{ds} - R\sqrt{1+\frac{2R}{r}}\,i_2 = -\frac{RE}{r}\tanh s \tag{53}$$

For the special case where $L/2\ RT = \sqrt{1+2R/r}$, the solution to equation 58 is

$$\frac{i_2}{I_0} = -\frac{R}{r\sqrt{1+\frac{2R}{r}}}\left(\frac{E}{I_0R}\right)(1+2s^2\tan^{-1}s^2) + \left(\frac{c}{I_0}\right)s^2 \tag{54}$$

where the line voltage and the constant of integration are evaluated from the boundary conditions that at $t=0$, $i_2 = I_0$, and at $t=1$, $i_2 = -I_0$,

$$\frac{E}{I_0R} = \frac{\frac{r}{R}\sqrt{1+\frac{2R}{r}}\left(1+\frac{s_1^2}{s_0^2}\right)}{1-\frac{s_1^2}{s_0^2}-2s_1^2(\tan^{-1}s_0^2-\tan^{-1}s_1^2)} \tag{55}$$

$$\frac{c}{I_0} = \frac{1+r\frac{R}{\sqrt{1+\frac{2R}{r}}}\left(\frac{E}{I_0R}\right)(1+2s_0^2\tan^{-1}s_0^2)}{s_0^2} \tag{56}$$

in which s_0^2 is the value of s^2 at $t=0$, and s_1^2 is the value of s^2 at $t=1$, so that $s_0^2 s_1^2 = 1$.

Figure 16 (left). Per-unit trailing brush contact voltage with line resistance in place of of noncommutating inductance

Figure 17 (right). Per-unit peak value of trailing brush contact voltage with line resistance in place of noncommutating inductance

The trailing brush contact voltages for typical values of line resistance for this special case are plotted in Figure 16, and the manner in which the line resistance limits the peak value of the trailing brush contact voltage is shown in Figure 17. For values of per-unit line resistance above 10, the peak value of the trailing brush contact voltage is given by

$$\frac{R_l \hat{i}_l}{2IR}\Big|_{l=1} = \frac{\pi}{2}\sqrt{\frac{r}{2R}} \qquad (57)$$

$$\frac{L}{\delta NT} = \sqrt{1+\frac{\delta R}{r}}$$

where

$$\frac{r}{2R} > 10$$

The line current ripple of course decreases as the line resistance is increased, being equal to 0.55 at a per-unit line resistance of 5, and equal to 0.87 at a per-unit line resistance of 100, for the particular value of reactance voltage being considered. An infinite amount of line resistance would be required to produce constant line current, so that the physical reason for the difficulty in obtaining a general solution to equation 40 in Appendix IV can be appreciated, since constant line current is assumed in this equation without regard to whether inductance or resistance is used to hold the line current constant.

The ability to control the magnitude of the voltage pulses by means of line resistance, as indicated in equation 57, offers interesting possibilities for research as to the threshold of damage to brushes and commutators as commutating conditions become severe. On the other hand, in order to test the commutating ability of brushes under simulated operating conditions,[11,15] no more resistance should be used in the line than occurs in actual machines, if erroneous results are to be avoided.

Appendix VI. Commutation Tester

Since the accuracy of prediction based on mathematical analysis of the commutation performance is limited by the assumptions, it is desirable to find the exact effects of deviations from the idealized conditions by direct measurement on a test machine in which the commutation phenomena can be reproduced at will. The test machine should represent closely the actual operating conditions, but because of the intricacy of the problem, provision should be made for suppressing the effects of all but the particular factors under investigation.

Figure 18. Commutation Tester

Figure 19. Commutation tester connected so as to measure commutating reactance

The commutation testing device shown schematically in Figure 18 is a counterpart of the equivalent circuit in Figure 3, and the commutating conditions which it can represent are limited to the same degree. Essentially, the commutation tester is a mechanical inverter which consists of a commutator with an even number of bars in which alternate bars are connected to one collector ring, and the remaining bars are connected to another collector ring on the same shaft. The shaft is mounted in bearings and is driven by a motor at the desired speed. The commutator brushes span one bar and are made of the same brush material as those of the machine being investigated. Two silver graphite brushes are used on each collector ring so that the contact voltage drop is negligible even at the highest currents to be carried. An inductor representing the commutating coils is connected between the collector brushes, and another inductor representing the noncommutating coils is connected in series with a low-impedance battery to the commutator brushes.

A short-circuiting switch is provided for the commutating inductor so that after each test reading the switch may be closed and a test measurement made immediately of the brush contact resistance, at the same value of line current. This cancels any error due to changes in the brush film, and allows the test readings to be expressed in the per-unit system. The accuracy of this measurement is good because the readings are direct, and no correction of the readings is needed for counter electromotive force as would occur if field excitation were present in the test machine.

Continuous display of commutation is made possible by the cyclic repetition of initial conditions, so that the effects of changes in circuit conditions are immediately evident. The advantages of using a stationary coil instead of a rotating coil to represent the commutating circuit lie in the ability to change the amount of inductance, in the ease with which direct measurements may be made, and in the separation of induced and generated voltages so that simulated generated voltages may be introduced directly into the commutating coil, if desired.

Values of the brush terminal voltage measured with a d-c voltmeter on a commutation tester are shown in Figure 7, from which it can be seen that this voltage is a nonlinear function of speed. The fact that the brush terminal voltage increases as the speed increases has been pointed out by Gano Dunn,[1] but a method for calculating the amount of the increase and the application of the result to commutation performance has not been presented. This voltage offers a readily measured quantity with which calculations based on circuit data may be compared.

Gano Dunn suggested that the brush terminal voltage be measured on an armature removed from the field and driven at rated speed, with rated current passed through the brushes from an external source. One objection to this method is that an additional voltage is generated by the motion of the commutating coils through the stationary magnetic field of armature reaction set up by the current even with the field poles removed. Another objection is that the absence of the field poles may reduce the inductance of both the commutating and noncommutating coils below their operating values. However, if in order to meet this latter objection, the armature were rotated in its normal position between the field poles with the field unexcited, pole face eddy-current and hysteresis losses due to slot flux pulsations may distort the measurements.

The use of a stationary armature in its normal position between the field poles and connected to a mechanical inverter as shown in Figure 19 overcomes the objections to testing with a rotating armature. Referring to Figure 7, it will be found that for the usual machine, at a per unit brush terminal voltage of 4 or above, the reactance voltage can be read directly, and from this the amount of inductance in the commutating coil can be determined.

Cathode-ray oscilloscope studies with the commutation tester are valuable in obtaining a detailed picture of the brush contact behavior under various commutating conditions. The ordinary oscilloscope is not suitable, however, since the presence of damped radio frequency oscillations introduced by impulse excitation of the interturn capacitance together with low frequency patterns set by the commutation period will result in hash on the normal oscilloscope screen with a re-current sweep. An oscilloscope with an accelerating potential of the order of 10 kv (light output increases as the square of this potential), with a long-persistence screen, and with a trigger circuit to initiate a single sweep of several microseconds duration will provide satisfactory results.

In order to find the relation between brush life and reactance voltage, two com-

Figure 20. Per-unit brush life

mutation testers were built and operated according to Figure 18 as follows:

Commutator diameter, inches	1.625
Number of bars	24
Brush size, inches	$^7/_{32} \times {}^9/_{16}$
Brush grade	Resin-bonded graphite
Initial brush pressure, pounds per square inch	6
Brushholders	Cartridge type
Commutator runout, inches	Less than 0.0006
Bar-to-Bar runout, inches	Less than 0.0002
Speed, rpm	5,000
Current, amperes	3 (24.4 amperes per square inch)
Ambient humidity, per cent	40 to 60
Brush temperature, degrees centigrade	50 to 70

Inductances (air core coils)

Test Number	L/2 millihenrys	$L_a/2$ millihenrys	L_a/L
1	0.391	5.1	13
2	0.204	2.5	12.3
3	0.086	1.15	13.4
4	0.037	0.53	14.3
		Average	13.2

The brushholders were assembled so that when one brush was in full contact with a bar connected to one ring, the other brush was in full contact with a bar connected to the other ring. Selected ball bearings with tight radial fit were used, and finger-spring axial loading was applied to reduce dynamic commutator runout. The commutators were diamond-turned in their own bearings, then dynamically balanced, and the brushes were sanded and run in until fully seated before each test. A 115-volt, 60-cycle-per-second bar-to-bar test was made every 100 hours to check for short circuits occurring from carbon between bars. The collector ring brush drop was less than 0.05 volt.

The test sequence on one commutator was 100 hours operation with the commutating coil in the circuit, then 100 hours with the commutating coil short-circuited, then with reversed polarity for 100 hours with the commutating coil in the circuit, and then another 100 hours with the commutating coil short-circuited. The test sequence on the other commutator was similar except that the first run was made with the commutating coil short-circuited, and the second with the commutating coil in, and so on. In this way, changes in the condition of the contact film were compensated.

Brush wear measurements were taken after each 100-hour period. Normal brush life was taken as the average of the 16 runs with the commutating coil short-circuited, and was 12,800 hours per quarter-inch. This is typical of life test experience with this brush grade on small commutating-pole machines, but it should be pointed out that there was a substantial decrease in brush life as the noncommutating inductance increased even on the test runs for which the commutating coil was short-circuited. This means that circuit inductance should not be neglected even for brush life testing on collector rings.[13]

Readings of brush terminal voltage were taken every four hours, with the commutating coil both in the circuit and momentarily short-circuited, the current being held constant for both conditions by means of a rheostat adding less than an ohm to the circuit. The brush contact resistance was taken as the average for each test of the readings of brush terminal voltage immediately after the commutating coil was short-circuited, when divided by the line current. A cross-check was maintained on the contact resistance by using the measured per-unit brush terminal voltage in Figure 7 to find the per-unit reactance voltage.

The results of this series of tests are shown in Figure 20. The line drawn through the test points indicates that

$$\text{per-unit brush life} = 0.28/\left(\frac{L}{2RT}\right)^{1.43} \qquad (58)$$

beyond the point where abnormal electrical wear begins. The fact that abnormal electrical wear begins near the value $L\,L_a/L+L_a = RT$ above which high-voltage pulses are predicted, is a strong confirmation of the theory. Other tests with the same conditions except with a copper graphite brush grade have shown the same relation between brush life and reactance voltage as given by equation 58, except of course with a lower base brush life and a lower contact resistance. Although it is too early for general conclusions, this may prove to be a universal brush life correlation, in which case the commutating ability of a particular brush grade could be determined over a wide range of commutating conditions from the results of a minimum of testing.

Discussion

A. F. Puchstein (Jeffrey Manufacturing Company, Columbus, Ohio): The subject of commutation is not simple even if the complete differential equations could be integrated. Historically, the development followed the course: (1) Empirical (examples are, machines spark inherently if core length is made greater than 14 inches, current per brush arm should not exceed 200 amperes). (2) Mathematical. Present paper is an example. They flourished around 1900 and led to such rules as[1]

$$\frac{RT}{L} > 1, \frac{RT}{A} > 1$$

where,[1]

$$A = \frac{L^2 - M^2}{L} \text{ and so forth.}$$

However, some details still remain to be worked out. (3) Semiempirical. These solved the problem for most practical purposes. They go all the way from considering only the effect of local slot and end-leakage fluxes to more elaborate summations of different inductive and speed electromotive forces. They may consider only one coil or a group of coils short circuited simultaneously. Most commonly, they assume sinusoidal or straight line reversals. Dreyfus[2] assumed piecewise straight-line reversals for coil groups. Menges in Holland about 40 years ago proposed a method in which the main part of the armature winding provides a shunt path around the brush contact.

Among contributors we find the names of Arnold,[4] Punga,[5] Hobart, Hawkins,[6] Press,[7] Kennedy,[8] Pichelmayer, Rüdenberg, Bewlay, Lamme,[9] Rezelman, Shenfer, La Tour, Girault, and Rothert.

Mr. Olney's paper is an interesting attempt to extend the theory from the viewpoints of mathematics and physics. From the viewpoint of the practicing engineer, the methods now in use are probably as satisfactory as it will be possible to make any method, considering ease of application, dependability, and the fact that the effects of such factors as the following are exceedingly complex and difficult to evaluate or predict: brush and bar materials; instantaneous current density and direction; instantaneous temperatures; chemical and physical constitution; kind of atmosphere; contact-drops; density of energy concentration and amount to be dissipated; heat dissipative capacity; spark and arc phenomena; vibration; mechanical factors; currents in cross or equalizer connections; dissymmetries of various kinds; brushes not exactly 180 degrees apart, or edges nonparallel, and so forth.

Add to these the fact that Olney's equations omit the effects of speed electromotive forces in the commutation zone, mutual inductances between armature coils, more than one bar under a brush, eddy currents, coupling with field coils, type of winding and possibly capacitance effects, and we have some idea of the difficulties involved in obtaining real precision.

The author does not take up the question of criteria as such or the way in which the information is used. Perhaps, the aim is more to pave the way for the commutation test arrangement given in Figures 18 and 19 of the paper. For criteria, there are available reactance voltage, sparking voltage,[1] volts between bar and brush tips, contact-drop, contact current density, watts and watt-seconds per unit area, volts between bars under a brush, volts across brush tips, and so forth. Their values may be average, effective, instantaneous, or maxima (usually taken at last moment of short circuit when $t = T$).

The idea of an equivalent network is novel. The test arrangement proposed uses two different inductances. It should simulate the commutating conditions quite accurately when the brush covers one bar or less. If the brush covers more than one bar, the simulation may be expected to be less exact, so that the need for further development may be indicated. However, for controlled brush-material life and comparison tests, the arrangement described probably will be as satisfactory as any. Arnold[4] and assistants of Karlsruhe many years ago used another test arrangement.

For most readers, the regular system of units will be more convenient than the per-unit system. Also, it is not certain that idiosyncracies in the physical phenomena can be avoided by changing the system of units.

Appendices I and II of the paper appear to be useful mainly for cross-checking. Presumably, Appendix III can cover Appendix IV approximately but in a broader way if we let L_a become large, so that L/L_a approaches zero in equations (32 and 34). We probably shall not obtain a solution satisfactory from the mathematical standpoint until new approaches to the integration, or machine methods, are developed. Perhaps, since $RT/(T-t)$ and RT/t do not actually go to infinity at $t = T$ and $t = 0$, other forms easier to handle and which represent the physical phenomena with comparable accuracy or even new functions to represent the solution, may be discovered.

For computation the following expressions[7] (with numerical work to illustrate them), which are based on similar assumptions but retain more terms, are quite convenient. At the last moment of short circuit when $t = T$ with $L < RT$, the time rate of change of current is

$$\frac{di}{dt} = I_c \times \frac{2R+2r+w+e}{RT-L}$$

$$= 10 \times \frac{(2\times 0.1+2\times 0+0.002+0.2)}{0.1\times 0.001-0.00005}$$

$$= 80{,}400 \text{ amperes per second}$$

and

$$L\frac{di}{dt} = 0.00005\times 80{,}400 = 4.02 \text{ volts}$$

where R, T, L, and t have the usual meanings. Let their values be 0.1 ohm, 0.001 second, $L = 0.00005$ henry, $t = 0$ to 0.001 second.

a = contact area under a brush = 0.2 inch × 1.0 inch = 0.2 square inch
i = value of current in coil at time t, amperes
r = resistance of lead between coil and commutator bar = 0.0 ohm
w = resistance of an individual armature coil = 0.002 ohm
I_c = current per armature path = 10 amperes
$I_c e$ = electromotive force generated in short-circuited coil by speed action

If coils are full-pitch with brushes in geometrical neutral it is proportional to I_c as indicated, = 0.2 volt per ampere. In the more general case, for any particular load replace $I_c e$ by E, say, where E is the speed electromotive force per coil due to the flux which enters or leaves the armature core and end connections at the commutation zone. This will be positive or negative depending upon which is the stronger, armature or field (or commutation pole if present). Now, let e_s = volts between trailing bar—and brush-tips at the last moment when $t = T$, then

$$e_s = I_c(2R+2r+w+e)\frac{RT}{RT-L} = 10\times(2\times 0.1+2\times 0+0.002+0.2)\times \frac{0.1\times 0.001}{0.00001-0.00005} = 8.04 \text{ volts}$$

This also is equal to

$$I_c(2R+2r+w+e)+L\frac{di}{dt} = 10\times(0.02+0+0.002+0.2)+4.02 = 8.04$$

Average reactance voltage

$$RV = L\left(\frac{di}{dt}\right)_{avg} = L\frac{2I_c}{T} = 0.00005\times\frac{2\times 10}{0.001} = 1.00$$

Energy stored in inductance

$$= \frac{LI_c^2}{2} = \frac{0.00005\times 10^2}{2} = 0.0025 \text{ watt-second}$$

Average contact drop at uniform current density

$$= 2I_c R = 2\times 10\times 0.1 = 2.0 \text{ volts}$$

Current across contact for a voltage drop

$$e_s i_s = \frac{e_s}{R} = \frac{8.04}{0.1} = 80.4 \text{ amperes}$$

Contact current density

$$i_d = \frac{e_s}{R_a} = \frac{8.04}{0.1\times 0.2} = 402 \text{ amperes per square inch}$$

This is also equal to contact current density at the last moment

$$i_d = \frac{T}{a}\frac{di}{dt} = \frac{0.001}{0.2}\times 80{,}400 = 402$$

corresponding contact loss at this density

$$P_d = \frac{e_s^2}{R_a} = \frac{8.04^2}{0.1\times 0.2} = 3{,}225 \text{ watts per square inch}$$

$$= i_d^2 R_a = 402^2\times 0.1\times 0.2 = 3{,}225$$

contact loss for whole area with 402 amperes per square inch would be

$$P_s = \frac{e_s^2}{R} = \frac{8.04^2}{0.1} = 645 \text{ watts}$$

contact loss for uniform current density would be

$$= 2I_c \times \text{volts drop per brush} = 2\times 10\times 2 = 40 \text{ watts}$$

$$= (2I_c)^2 R = (2\times 10)^2\times 0.1 = 40$$

The above equations, of course, do not apply strictly when the brush covers more than one bar. However, if R, L, and other factors are suitably interpreted they are usable and have been so used for many years.[10] For the value of e_s required to produce a spark between commutator and brush, see abstract of an article by Liska[11] written in 1909.

ATURE, LIEBE. *Electrical World* (New York, N. Y.), February 18, 1909.

Paul W. Franklin (Bendix Aviation Corporation, Teterboro, N. J.): The writer would like to start his discussion with the part of the paper which appears to him of particularly practical importance, namely, a brush testing device.

It is the writer's belief that a testing device, standardized by the AIEE, National Electrical Manufacturers' Association and all major brush companies, with regard to commutation ability and wear, would be of considerable value to everybody concerned. This is particularly the case for the aircraft industry with regard to brush life at high altitudes, where actual environmental tests are expensive. The device suggested by the author appears to be very promising, provided that the experimental conditions are carefully controlled. It is hoped that the paper furnishes the incentive required for such standardization.

It may be of interest to mention here the limitation of the general theory of commutation, as developed by Arnold and advanced by Dreyfus, Trettin, Richter and others, the more, as these limitations have a particular bearing upon a theory based on brush contact resistance.

Arnold, in his book dealing with the d-c machine, mentions the clues indicating these limitations. Discussing certain commutation oscillograms, he notes strong peaks and irregularities in the observed curves, as compared with the calculated values. He also notes, after a very thorough theoretical derivation of the shape of the interpole flux and pole shoe, that practical experience indicates that a narrower interpole shoe, than obtained by theory, will give good commutation.

The first clue, in the writer's opinion, is an indication of the effects of brush vibration, whereas the second may have a bearing on flux fringing, varying zigzag leakage of the commutating slot, and the shape of the actual brush contact area.

Calculations performed on the commutator data presented by the author furnish the following results.

The time required to pass by one commutator bar at the speed of 5,000 rpm is 5.0×10^{-4} seconds. Let us now assume, that the bar-to-bar run out is, as indicated, 2×10^{-6} inches, and let us further assume, that the brush is moved with constant acceleration for this distance during half the time given. During the travel of half a commutator bar, the brush is pushed up or down for the run out of 2×10^{-6} inches. The constant acceleration required for this is of the magnitude of 16 g's* and gives an indication of the severity of the vibrations. Incidentally, these vibrations may cause the designer to consider his brush pressure not so much as pounds per square inch, but rather rate it in pounds per pound brush weight.

Now using the formula given by Dr. Neukirchen in his book[1] (page 3) and assuming the same values for M_1 and M_2 and a difference of 0.001 inch between the commutator and brush radius, we obtain a theoretical contact width of 1/16 inch, as compared with the brush width of 7/32 inch upon which the author's theory is based.

Undoubtedly the author found that the brush surface was uniformly shiny, and therefore either the Hertzian contact equation does not apply or a continuous infinitely small rocking between brush and commutator must take place.

Evidence of such rocking, or rather reseating, can be observed very often on aircraft machines for low voltage, which have a comparatively wide brush and a high number of ampere-conductors per inch. A change of contact will amount essentially to a change of neutral and make itself felt in the amount of required field current for a given condition. It also can be observed, that, if an aircraft generator is run at low speed, then at high speed, and again at low speed, that the field current at low speed after the high speed run has changed from its original value, more than may be accounted for by heating. Definitely, something has changed under the brush; let us call it contact location, shift in neutral, change in film, friction coefficient or eddy current distribution, but a change is evident and also is felt electromagnetically.

Of course, this particular reseating depends upon the stability of the brush holder.

Most of these phenomena are not being noticed on conventional machines, either with low speed, or low design parameters. They are undoubtedly felt however at highly compacted machinery.

In the writer's belief, this goes to show, that the value of a theory of commutation based on steady brush contact is greatly impeded by the erratic nature of this contact. This applies particularly to high-speed high-density machines.

It would have been of interest if the author had shown pictures of his oscillograms and compared these with the calculated current and voltage time curves. Also, it may be of value if the author explains the nature and location of the noncommutating coils interlinked in the commutation process.

The author's experience, that, among other things, brush life is a function of the reactance voltage (in the case of interpole machines, a function of the uncompensated reactance voltage) is fully borne out by the experience of the writer.

The writer feels that Mr. Olney has contributed an interesting and important paper to the art, which again bears out the vast complicity of the commutation problem, and wishes to congratulate him.

Frank D. Olney: Mr. Puchstein describes design methods which have existed for a long time—that is, methods by which commutator machines are designed largely by reference to similar machines and in which there is no general basis for designing from basic dimensions as has been developed for a-c machines. Obviously, a starting point is needed, some benchmark common to all commutator machines on which design formulas may be based with a reasonable expectation that the calculations can be verified by experiment. However, a generalized approach such as this is expected to be of interest mainly to engineers engaged in the development of new and improved machines, and not necessarily at present to those responsible for maintaining an established line of machines.

Improved commutator machines and electric brushes are urgently needed; for example, contrary to a general feeling that brush treatments have solved the altitude problem in aircraft commutator machines, actually trouble has been avoided largely because most flight time has been below 20,000 feet, and for projected aircraft involving long flights of 50,000 feet and above, the brush problem is as serious as it ever was. Again, commercial commutating-pole machines in general cannot be loaded in excess of twice rated load even momentarily without danger of permanent damage to the commutator, even though the operator may not be provided with control over the machine sufficient to prevent overloading. Other serious operating problems which demand a more vigorous analysis are those of flashover, radio noise, and short-circuit currents. The conclusion is inescapable that the commutating pole has not proved to be a complete answer to the commutation problem, and that present electric brushes are not stable enough under actual operating conditions.

All the works mentioned by Mr. Puchstein, and many others including German, Russian, Japanese, and French contributors, were examined during this investigation and were found to comprise largely speculation as to the nature of the brush contact film as for example in Neukirchen's work, or else of assuming the answer concerning the shape of the current reversal in the commutating coil as for example in Dreyfus's work, and all these references are practically devoid of experimental evidence to support any conclusions. For example, in the test arrangement cited by Mr. Puchstein which is shown in Figure 327 on page 375 of "Die Gleichstrommaschine" by E. Arnold, the measured value of commutating reactance is not given, so his data is useless to the practicing engineer. This situation is not unknown to these contributors. Indeed, to quote Arnold, "The longer the problem of commutation is studied the less possible it becomes to investigate this process analytically." However, there is no evidence that any of these writers suspected the existence of a major discrepancy between the circuits described by their mathematics and the circuits used for their tests. For example, Karasiov assumes constant line current during commutation in his calculations, and yet his test arrangement uses a series resistance on a 220-volt line which, as shown in Appendix V of the present paper, does not provide constant current, and will yield erroneous results.

Anyone familiar with the 60-year record of brush and commutation data and the numerous attempts to correlate this data, cannot fail to be impressed with the difficult factors involved. Yet the analysis and tests in this paper show that the inclusion of the measured brush contact resistance under the specific commutating conditions being considered, and the inclusion of the noncommutating inductance as a major factor in the basic magnetic geometry of commutator machines, will enable a general correlation of machine and brush commutating characteristics to be established for design work so as to be applicable to any

*Where g is the acceleration of gravity.

commutator machine. That this is reasonable physically is shown by the analysis in Appendix III where resistance commutation is seen to be very nearly just the interruption of current in an inductive circuit by means of contacts in which the contact area decreases at a constant rate, so that the problem of wear of sliding contacts approaches that of the wear of stationary contacts used in control circuits. The confirmation of this viewpoint has been shown by tests on three widely different brush grades to date—copper graphite, resin-bonded graphite, and electrographitic. These tests were made with simple equipment which can be built by anyone with access to a machine shop.

Further extension of the analysis in Appendix III to the case of commutating pole machines, to brush overlaps different from one segment, and to unsymmetrical windings shows that the form of equations 32 and 34 is unchanged and only the coefficients are different, so that a general correlation of machine and brush characteristics is a reasonable objective. While it is true that the problem is not simple, each factor can be treated as a variation from an idealized machine. And Mr. Puchstein apparently does not actually feel that the problem is impossible of solution because of "exceedingly complex and difficult factors," since he finally states that when these "factors are suitably interpreted they are usable."

Contrary to Mr. Puchstein's statement that the paper does not take up the question of criteria, Figure 20 gives the commutation criteria in the form needed by the designer, that is, at what reactance voltage abnormal electrical brush wear starts, and what magnitude of abnormal wear is expected as that value of reactance voltage is exceeded, as it must be with certain machines. All mention of sparking is deliberately omitted from the paper in order to avoid the pitfalls of unconfirmed speculation.

Regarding the numerical example given by Mr. Puchstein, this example is the same as that given by him in a letter to the AIEE editor in July 1943.[1] The numerical values given for the parameters apparently do not apply to a specific machine since there is no indication as to how the values are calculated or measured. The reactance voltage for this case is 0.5 per unit, so that the commutation would be expected to be almost perfect, and no difficulty will be encountered from the indeterminate expressions which are found above this value of reactance voltage when Mr. Puchstein's method of attack is used. Further, any analysis based on only the last moment of commutation fails to yield the correct value for the average contact drop, which in this case is 2.8 volts instead of the 2.0 volts given by Mr. Puchstein. However, the outstanding thing about this example is that no test results are given to support the calculations, and so while this example might be helpful for explanation, it cannot be used for prediction, since there is no way of knowing whether or not the data is sound.

Mr. Franklin's constructive comments are quite helpful, and the author agrees particularly with his point of view on a standard commutation testing device.

It is true that the calculations apply only to cases where there is a mechanically perfect contact between brush and segment, and while these conditions can be obtained in controlled tests with a diamond-turned commutator using a carefully run-in brush as shown by Figure 7, yet we know that the trailing edges of the brushes are burned back after a short time on life test so that there is not full lateral contact between the brush and segment. We have no way at present of predicting analytically the rate of brush wear under specific commutating conditions—when such information is available, the calculated and test curves of brush wear will probably diverge as a result of this lateral brush wear.

As far as instantaneous irregularities in the brush-to-segment contact are concerned, it seems reasonable to take a statistical view of the situation. For example, in the brush life tests reported in Figure 20, there were 3,200 hours of running time. At 5,000 rpm with 24 segments passing the brushes each revolution, in that period of time there were 23,000,000,000 individual contact separations—certainly enough to average out any deviations. Oscillograms of the commutation process were omitted from the paper because they tend to be confusing unless one is familiar with the techniques involved, and thus they are not of general interest.

Mr. Franklin's question concerning the nature of the noncommutating coils may be clarified by reference to Figure 1 of the paper, where these coils are in the slots marked "a." The noncommutating coils are those with a magnetic axis in quadrature to the main field direct axis, and so they are the working coils of the machine in which the output is generated. Neglecting machine dissymmetry, the ratio of noncommutating to commutating inductance is roughly equal to the ratio of the number of slots under the field poles to the number of slots in the commutation zone.

In regard to brush life as a function of uncompensated reactance voltage in commutating-pole machines; when the brush overlap is equal to one segment it is possible to compensate the reactance voltage by means of commutating poles. With other overlaps a compromise is required, depending on the brush contact resistance, on the ratio of noncommutating to commutating reactance, and on the magnitude of the reactance voltage. That is, the proper commutating-pole voltage for optimum commutation is not in general exactly equal to the reactance voltage. Therefore, it is not strictly correct to say that brush life is a function of the uncompensated reactance voltage in commutating-pole machines—at least until this point has been thoroughly proved by carefully controlled life tests. This point, of course, is outside the scope of the present paper.

Current in Equalizer Connections of D-C Machine Armature Windings

T. M. LINVILLE
FELLOW AIEE

D. P. STRANG
ASSOCIATE AIEE

Synopsis: Equalizer connections are a necessary part of d-c machine armature windings having more than two circuits. Nearly all machines of medium and large sizes and many small machines for special purposes are in this category. These connections cause substantially equal currents to flow in the circuits of the armature winding resulting in minimum losses, minimum temperature rise, and uniform commutation at each brush arm. This paper determines the current which the connections carry when the excitation of the field poles is unbalanced. From the results, the size of the connections to meet a specified temperature rise, under given unbalanced conditions, can be determined. The paper explains the reasons for the use of equalizer connections and describes how they work.

EQUALIZER connections or equipotential connections as described by Arnold[1] have been used for many years but their function has not been fully understood, as pointed out by Moore.[2] A well-known description of them is given in the college textbook by Langsdorf.[3] Their importance for multiplex windings has been emphasized by Nelson.[4] However, a practical analysis of the currents which flow in them has not been found in the literature and only a partial theoretical analysis has been available.

The purpose of the paper is to determine the current carried by the equalizer connections under unbalanced conditions. For example, these conditions might be: (1) that machines are to be built which will not overheat and will continue to commutate in spite of temporary roughness of their commutators; and (2) in case of damage to a field coil, the coil may be removed from the field circuit without affecting the operation of the machine except that operation thereafter will be at reduced voltage as required to avoid overheating of the remaining field coils.

During the war, in the construction of propulsion machinery for naval vessels and machinery for other military purposes, it was vital that operation be undisturbed by failure of a field coil and that repairs be made when convenient rather than as an emergency. In these cases, the equalizer connections and other windings were made to meet the concrete condition of loss of a field coil. These machines also were made to meet the test condition that the brushes of a brush arm could be removed without disturbing commutation. When the current in the equalizer connections is known for such conditions, the required size of conductor for them can be determined. The results of the paper can be applied to determine the current for all conditions of unbalanced field excitation.

In view of the fact that the best conditions are obtained when an equalizer connection is provided for every commutator bar, full or 100-per cent equalization is taken as basic for the paper. Furthermore, the results are expressed for machines having only one turn per armature coil.

The results can be extended readily to cover machines with less than 100-per cent equalization and more than one turn per armature coil.

Results

As shown in the analysis to follow, the maximum current in any equalizer connection for any machine* when excitation is removed from one pole with any excitation of m_f ampere turns on each of the remaining poles, is

$$i_e = (P-2)(4m_f/\pi P)\,(\sin^3(\alpha/2)\cos(\omega t/2) + (1/3)\sin^3(3\alpha/2)\sin(3\omega t/2)) \quad (1)$$

where

$$\alpha = \frac{\pi P}{2S_c} \quad (2)$$

and

P = number of poles
S_c = number of bars in commutator
ω = electrical radians per second

The corresponding rms current* for each equalizer connection and for the whole of the equalizer winding is

$$I_e = \delta(8m_f/\pi)\sqrt{(1/2)\,[\sin^4(\alpha/2) + (1/9)\sin^4(3\alpha/2)]} \quad (3)$$

when the value for δ is taken from Table II.

For practical machines it generally is true that

$$\sin(\alpha/2) = \alpha/2 \quad \text{and} \quad \sin(3\alpha/2) = 3\alpha/2 \quad (4)$$

Therefore, equation 3 becomes

$$I_e = 3.53 m_f P^2/S_c^2 \quad (5)$$

These results are derived by analysis and are substantiated by comparison with test results (limited to one 4-pole machine) and by comparison with analysis of a simplified 4-pole machine, Appendix II.

Assumptions

The current in the equalizer connections is affected by dimensions of the air gap and by the shape and spacing of the main pole tips and by the interpoles. Variation of these dimensions causes the resulting currents in the armature winding, producing armature magnetomotive forces, to be more or less concentrated in the spaces between main poles. Thus the distribution of armature magnetomotive forces is of the nature of a square wave, as shown in Figure 1. With dimensions

* In 4-pole machines where the equalizers do not form a ring, equations 1, 3, and 5 must be multiplied by 2.

Paper 50-192, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 3, 1950; made available for printing August 25, 1950.

T. M. Linville and D. P. Strang are both with the General Electric Company, Schenectady, N. Y.

found in practice it is considered that the fundamental and third harmonic of the square wave represent the actual magnetomotive force wave. In some cases, this may be optimistic, particularly with respect to the rms, value of current. The influence of saturation is considered negligible.

Discussion of Results and Comparison with Test Results

In Figure 6, curves are shown as obtained by test measurement and as calculated from test data. In Figure 9, these curves are compared directly with calculated curves. The rms value of current in the equalizer connections determined from test is 14.9 amperes (see Appendix I) as compared with 12.0 amperes calculated from equation 5. Comparison of equation 5 with the result of the alternative method of analysis given in Appendix I, equation 20, shows that the two results have common coefficients and numerically give 10.7 amperes for the method of Appendix I compared to 12.0 amperes for equation 5. The method of Appendix I assumes that the equalizing current in the armature coils is distributed symmetrically about the interpole axis in the manner of $i_s = A(1+\cos\phi)$ as shown in Figure 6. Analysis of the test results suggests this assumption.

An additional comparison is afforded by Appendix II, in which a simplified machine with only 12 armature coils is analyzed mathematically. The wave shapes found by this analysis, shown in Figure 8, are similar to the test results, Figure 6, and furthermore, the rms equalizer current agrees well with equation 20 developed in Appendix I. This agreement is shown by comparison of equation 46 with equation 47.

The comparison of test curves (broken lines) with calculated curves (solid lines) shown in Figure 9 illustrates the importance of equalizer connections of low impedance. Harmonics which appear in the current in the armature coils, curve *C*, Figure 9, cause relatively little departure from the calculated current wave. These harmonics cause greater discrepancy between calculated and test currents in the equalizer connections, shown in curve *D*. This illustrates the amplification of harmonic currents in the equalizer connections. There are, of course, many factors in an actual machine to cause these harmonic currents. For example, in our test machine there are three slot openings in each pole face for a compensating winding which was disconnected during the tests. These slot openings in conjunction with the armature slot openings are responsible for the ripple in the test oscillograms, curves *C* and *D*, Figure 5, and for harmonic currents in the equalizer connections, curve *D*, Figure 9.

Function of Equalizers

One way to build the most into a d-c machine, in order to get the most out of it, is to construct it in such a way that every bar in the commutator is connected directly by equalizer connections to every circuit in the armature winding. If this is done, the power current will automatically divide equally between the circuits of the armature winding so that the heating will be minimum and will be uniformly distributed. Then the commutation will be the same at every brush holder arm. Operation can be continued when the commutator becomes rough, causing the brushes to bounce or when a bar is low and fails to contact the brushes, or when a field pole coil has failed and has been removed from the field winding circuit. Moreover, the voltage from bar to bar around the commutator will be minimum and will be distributed in an unchanging pattern.

Figure 2 shows equalizer connections which tie each commutator bar directly to each circuit. A ring winding is shown for illustration having four poles and circuits *a*, *b*, *c*, and *d*, in the armature winding. The brushes 2 contact this winding at four equally spaced points. Theoretically the machine with this armature winding will operate without the equalizer connections, 1. However, without them if the top right-hand one of the brushes 2 should momentarily be lifted out of contact with the winding, the current in branches *a* and *b* will be momentarily zero and will be correspondingly greater in branches *c* and *d*. Likewise, unbalance will be created if the resistance of the contact between this brush and the winding is momentarily greater than for the other brushes because of eccentric movement of the commutator or a spot on the surface or roughness. Such unbalance of current in the branches *a*, *b*, *c*, *d* cannot occur when the connections, 1, are present because the contact of any one of the brushes with the winding is then a 4-way contact. The power current divides between the branches *a*, *b*, *c*, and *d* independently of variations in the brush contacts by flow of current in the connections 1. Because of rotation of the armature, the illustration of Figure 1 holds for only a moment but when all points of contact between the winding and brushes, that is, all of the commutator bars, are connected together by similar connections 1, the conditions at any moment are as shown in Figure 2. Obviously, unless the currents in the branches *a*, *b*, *c*, and *d* are balanced, there will be excessive heating and, because the commutating

pole windings will be balanced independently of the currents in the branches, there will be sparking.

Of primary importance also, is the fact that in practice the electromotive force generated in the branches *a*, *b*, *c*, and *d*, without the connections 1, are not equal because the air gaps of the respective poles cannot be made exactly the same. If the electromotive force of branches *c* and *d* are not equal and opposite as they should be, then a current will flow through the bus ring 3 causing sparking. Under certain conditions it is possible that branches *c* and *d* will have harmonics (a ripple) in the electromotive force which will cause a ripple current to flow in bus 3 causing sparking. These currents in bus 3 will not flow when the connections 1 are present because a direct path of relatively low impedance is then provided for them. The flow of the currents sets up a magnetomotive force which "equalizes" the flux for all poles and, therefore, brings the electromotive force of the branches *a*, *b*, *c*, and *d* into balance. Therefore, only a small magnetizing current flows which normally is negligible in comparison with the power current.

It follows that the "equalizer connections" perform three principal functions, namely:

1. Cause the power current to divide between the paths of the armature winding independently of the condition of the brushes or the commutator surface, resulting in minimum heating of the winding and uniform commutation at each brush arm.

2. Cause the flux from each of the poles to be "equal" and allow the necessary magnetizing currents to flow in the armature winding; eliminate current flowing in the bus rings between brush arms; result in minimum core losses, minimum magnetizing current, no sparking from magnetizing current flowing to and from the brushes, and minimum voltage between adjacent commutator bars.

3. "Anchor" the two windings together in the special case of duplex windings and, in addition, to function 1 and 2, cause a fixed voltage between each bar and the bars next to it which in this case belong to a second winding. In this case there is in addition to the winding, *a*, *b*, *c*, *d* of Figure 1, another duplicate parallel winding connected to a set of commutator bars which are interleaved with the bars of the first winding. Study of duplex windings is beyond the scope of the paper.

Analysis

An understanding of the manner in which equalizing current flows in the armature winding and in the equalizer connections can be gained from an analysis built on Figure 3. It is obvious from Figure 3 that two armature coils spaced exactly two pole pitches apart and cross connected by equalizer connections form an elemental circuit in which no current will flow if the armature rotates while the flux from each of the four poles is exactly the same. When the flux from each of the poles is not the same, a current will flow.

In the diagram of Figure 3 consider that the top pole alone is excited. This is equivalent to having all poles excited equally except one which has no excitation, as though one field coil has failed and has been removed from the field circuit. As indicated by the numbers on Figure 3, the ratio of armature magnetomotive force to field magnetomotive force is 1 to 2, that is

$$m_a = 1/2 m_f \tag{6}$$

where m_a is the maximum amplitude of the armature reaction magnetomotive force, see Figure 1, and m_f is the unbalanced magnetomotive force applied to the top pole only. This relation is demonstrated by equation 43, Appendix II. The total armature magnetomotive force, half appearing on one side of the armature and half on the other, is equal to the field magnetomotive force, m_f. Since the elemental circuit rotates rapidly and has very little resistance compared to reactance, its flux linkages must be substantially zero at all times. However, there are a multiplicity of duplicate elemental circuits spaced uniformly around the armature to make the whole winding. Therefore, the linkages which current in

Figure 6. Analysis of test results

Curve D: Armature magnetomotive force
Curve E: Idealized armature magnetomotive force
Curve F: Idealized current in armature coils
Curve G: Idealized equalizer current

these coils produces in the elemental circuit of Figure 3 must be included. It follows that the space distribution of the armature magnetomotive force tends to be constant across each pole arc, the same as the distribution of field magnetomotive force, and for a 4-pole machine as illustrated in Figure 1 can be expressed by the Fourier series.

$$m_a = \frac{\sqrt{2}}{\pi} m_f \left(\cos\theta + \frac{1}{3}\cos 3\theta \ldots \right) \qquad (7)$$

where θ is the angle in mechanical radians with respect to the center line of the main pole.

The distribution of current around the periphery of the armature to give the magnetomotive force of equation 7 is obtained by differentiating the magnetomotive force

$$i_a = \frac{d}{d\theta} m_a = \frac{\sqrt{2}}{\pi} m_f (\sin\theta + \sin 3\theta \ldots) \qquad (8)$$

From this equation the current in each armature coil can be derived as a function of time in the following manner.

The current per sector of the armature winding consisting of one top and one bottom layer conductor is

$$i_s = \int_{\frac{\omega t-\alpha}{2}}^{\frac{\omega t+\alpha}{2}} i_a d\theta = (2\sqrt{2} m_f/\pi) \left([\sin(\alpha/2) \sin(\omega t/2) + (1/3) \sin(3\alpha/2) \sin(3\omega t/2) \ldots] \right) \qquad (9)$$

where ω is in electrical radians per second and

$$\alpha = \frac{\pi P}{2S_e}$$

when P is the number of poles and S_e is the number of bars in the commutator.

The harmonic currents in the top conductor are each exactly the same as the current in the bottom conductor except they are in reversed phase quadrature. Hence, the current in every armature coil is

$$i_c = (2m_f/\pi) \left([\sin(\alpha/2) \sin(\omega t/2) - (1/3) \sin(3\alpha/2) \cos(3\omega t/2)] \right) \qquad (10)$$

The current in each equalizer connection is equal to the difference between the currents of two adjacent coils of the winding which with the equalizer connection form a Y junction. The two coils have the same current except for the phase displacement of 2α radians. Therefore, the current in the equalizer connection which is the difference between the two is

$$(i_e = 4m_f/\pi) \left([\sin^2(\alpha/2) \cos(\pi t/2) + (1/3) \sin^2(3\alpha/2) \sin(3\omega t/2)] \right) \qquad (11)$$

The shape of this current is shown in Figure 9(D). In drawing the curve, sin α is taken as equal to α (with α being small).

General Solution

In the general case, the current, equation 11, modified as to amplitude to correspond to the general form of equation 6, flows continuously between one point on each equalizer ring and the armature winding.

The general form for equation 6 is

$$m_a = \frac{P-2}{P} m_f \qquad (12)$$

and when this is substituted in place of equation 6 it has the effect of multiplying equation 11 by $2(P\text{-}2)/P$.

The current divides in each ring, half flowing one way and half the other way around the ring. Accounting for this by dividing by 2, equation 11 becomes true for the general case when multiplied by $(P\text{-}2)/P$ or when

$$i_e = (4m_f/\pi) \; [(P-2)/P] \left([\sin^2(\alpha/2) \cos(\omega t/2) + (1/3) \sin^2(3\alpha/2) \sin(3\omega t/2)] \right) \qquad (13)$$

Equation 13 gives the current in each of two equalizer connections attached to a common commutator segment while the segment is passing through the arc from π radians on one side of the excited pole to π radians on the other side. Other equalizer connections in the same ring carry part of the same current but in diminishing amounts. A given equalizer connection sucessively carries the full current given by equation 13, then a part of it as its location in the ring changes with rotation of the armature. It is important to know the rms current in the ring which will be the same as the rms current in any equalizer connection and also the same as the rms current in the entire equalizer winding. For this rms current and for a given size of the equalizer connections and a given total weight of copper in the equalizer winding, the losses may be calculated. Or the size of conductor may be determined for given allowable losses.

The rms current in the equalizer winding of any machine will be the rms value of equation 13 provided the number of equalizer connections in each equalizer ring is factored into it. This is done by factoring $(P-2)/2P$ out of equation 13 and replacing it with a factor set up from Table I to account for the number of equalizer connections per ring and their respective currents.

In Table I the current in each equalizer connection of a ring is expressed in terms of

Table I. Factor for Mean Square Current

Sum of Each Column Times Factor

$P/2$ even no.: $\left(\frac{P-2}{2P}\right)^2\left(\frac{2}{P-2}\right)^2\frac{4}{P}\left[1+3^2+5^2+----\left(\frac{P-2}{2}\right)^2\right]$

$P/2$ odd no.: $\left(\frac{P-2}{2P}\right)^2\left(\frac{4}{P-2}\right)^2\frac{4}{P}\left[1+2^2+3^2+----\left(\frac{P-2}{4}\right)^2\right]$

the base factor $(P-2)/2P$. Every value is squared so that the sums may be taken to get the mean square. For this purpose the sum of the squares is multiplied by $4/P$ as the number of equalizers carrying equal current is always two and the total number of equalizers which are in a ring is $P/2$.

Therefore, the rms current is the rms value of

$$i_e=(8m_f/\pi)\delta\left([\sin^3(\alpha/2)\cos(\omega t/2)+(1/3)\sin^3(3\alpha/2)\cos(3\omega t/2)]\right) \quad (14)$$

where from Table I, when $P/2$ is an even number

$$\delta^2=\frac{4}{P^2}\left[1+3^2+5^2+\ldots\ldots\left(\frac{P-2}{2}\right)^2\right] \quad (15)$$

and when $P/2$ is an odd number:

$$\delta^2=\frac{16}{P^2}\left[1+2^2+3^2+\ldots\ldots\left(\frac{P-2}{4}\right)^2\right] \quad (16)$$

Numerical values for δ are tabulated in Table II.

Appendix I. Test Results and Analysis

The test machine was a 10,000-rpm 24-volt 4-pole 4-circuit-starter motor, shown schematically in Figure 4. It had 34 slots and commutator segments, and 100 per cent equalization. For the tests, one internal equalizer was removed and replaced by one of equal resistance on the outside of the commutator. Pickup wires were connected to each end of the test equalizer, wrapped around it to minimize inductive pickup, and connected to two slip rings. The slip rings were made of brass and fitted over the commutator. On each slip ring was a brush consisting of ten phosphor-bronze strips, to which the oscillograph was connected. The machine was driven at 3,600 rpm by an induction motor, and the d-c brushes were removed from the commutator. The commutating poles were removed from the machine and only the shunt fields were excited. The excitation was kept low to avoid overheating and to prevent saturation.

As a check on the test setup, two tests were made. First, a current of 10 milliamperes through the pickup brushes produced no "hash" from brush contact. Second, with one end of the test equalizer disconnected, no signal could be seen for any magnetic unbalance. Thus there was no inductive pickup.

Oscillogram, Figure 5(A), shows the equalizer current with balanced excitation applied. Oscillogram Figure 5(B), shows the equalizer current with approximately normal excitation on only one pole. This oscillogram is traced on curve A, Figure 6.

In Figure 6, curve A is the current in the equalizer connections as a function of position and, because of the large number of slots and equalizer connections, this current is proportional to the rate of change of armature current. Then the integral of curve A gives the current in the armature conductors as a function of position, curve B. The current in the armature slots is the sum of the current in the top and bottom conductors. Therefore, the slot current as a function of position, curve C, is the sum of the conductor current, curve B, and the negative of conductor current displaced 90 degrees. The integral of curve C gives the armature magnetomotive force curve D.

Before going further with the curves of Figure 6, two more test oscillograms are of interest. Using the same test setup, oscillograms of voltage between two adjacent commutator segments also were taken. Oscillogram Figure 5(C) shows the bar-to-bar voltage with a balanced excitation of 198AT/pole. Oscillogram Figure 5(D) shows the bar-to-bar voltage with 490AT excitation on only one pole. That the voltage of Figure 5(D) is balanced means that armature currents flow to balance the field. Thus one peak of curve D, Figure 6, opposes the applied magnetomotive force, and the other one excites the opposite pole. The amplitude of the armature magnetomotive force must be half of the applied excitation, neglecting leakage. The integration of curve C to obtain armature magnetomotive force of curve D gives a peak of 224AT, which is approximately half of the actual applied excitation.

Now let us analyze the curves, Figure 6. It is clear that the small peaks in armature current, curve B, tend to make the magnetomotive force curve D slightly unsymmetrical. Nevertheless, the armature current curve B, can be idealized as parts of sinusoids, as shown in curve F. This results in a magnetomotive force distribution curve E which is very similar to curve D. The derivative of the armature current curve gives an idealized equalizer current as shown in curve G.

From these idealized curves we can find

Figure 7 (left). Simple machine for analysis of Appendix II

Figure 8 (lower left). Analysis of simple machine

Curve H: Rate of change of armature current
Curve J: Current in armature coils
Curve K: Rate of change of equalizer current
Curve L: Equalizer current

Figure 9 (right). Comparison of calculated curves with curves from test data

Curve A: Armature magnetomotive force, equation 7 $m_a = 220\ [(\cos\theta + (1/3)\cos 3\theta)]$
Curve B: Current in armature slot, equation 9 $I_s = 41\ (\sin\theta + \sin 3\theta)$
Curve C: Current in armature coil, equation 10 $I_c = 29\ [(\sin(\omega t/2) - \cos(3\omega t/2)]$
Curve D: Current in equalizer connection, equations 11 or 1 $I_e = 5.3\ [(\cos(\omega t/2) + 3\sin(3\omega t/2)]$

an expression for equalizer current. In Figure 6, the area of one pulse of armature current is πA, and multiplied by the number of armature turns per radian, a, is equal to the peak value of the magnetomotive wave, m_a. Thus

$$A = \frac{m_a}{\pi a} \tag{17}$$

Similarly, the area of one pulse of equalizer current times the number of equalizer connections per radian, b, is the magnitude (B) of the armature current pulse. Thus

$$2A = \frac{2B}{\pi} \times \frac{\pi}{2} \times b$$

or

$$B = \frac{2A}{b} = \frac{2m_a}{\pi ab} \tag{18}$$

The rms value of equalizer current over the complete cycle is

$$I_e = \frac{B}{2} = \frac{m_a}{\pi ab} \tag{19}$$

Now if m_f is the excitation applied to one pole, we have $m_a = m_f/2$ and

$$I_e = \frac{m_f}{2\pi ab} \tag{20}$$

As a check, the excitation to get curve A was 490AT, and for this motor $a = b = 17/2\pi$. Thus,

$$I_e = \frac{2 \times 490 \times \pi}{(17)^2} = 10.7 \text{ amperes} \tag{21}$$

From the actual oscillogram the rms value of equalizer current is 14.9 amperes. Expressed in other terms

$$a = b = \frac{S_s}{\pi P}$$

and equation 20 becomes

$$I_e = \frac{\pi m_f P^2}{2S_s^2} \tag{22}$$

This result, true only for a 4-pole machine, can be compared with equation 5.

Appendix II. Analysis of an Elementary Machine

This analysis is intended to demonstrate, using a simple machine with equalizer connections, that armature currents equalize any unbalance in the applied excitation. Consider the configuration shown in Figure 7, with 12 armature coils, four poles, and six equalizer connections. Assume a uniform air gap, neglect resistance and leakage reactance of the windings, and consider only one pole excited. If the self inductance of one coil is

$$L_{11} = L \tag{23}$$

from the geometry of the machine we have mutual inductances given by

$$L_{14} = L_{15} = L_{16} = L_{17} = L_{18} = L_{19} = L_{1\,10} = -\frac{1}{3}L \tag{24}$$

$$L_{12} = L_{1\,13} = \frac{5}{9}L \tag{25}$$

and

$$L_{12}=L_{1\,11}=\frac{1}{9}L \tag{26}$$

Then taking E_{g1} as the generated voltage in coil 1 due to field excitation, the terminal voltage of coil 1 can be expressed as

$$E_1=E_{g1}-pL\left[i_1+\frac{1}{9}(5i_2+i_3-3i_4-3i_5-3i_6-3i_7-3i_8-3i_9-3i_{10}+i_{11}+5i_{12})\right] \tag{27}$$

Writing similar equations for the other armature coils gives

$$\frac{9}{pL}\begin{array}{lrrrrrrrrrrrr}
 & i_1 & i_2 & i_3 & i_4 & i_5 & i_6 & i_7 & i_8 & i_9 & i_{10} & i_{11} & i_{12} \\
\frac{9}{pL}(E_1-E_{g1})= & -9 & -5 & -1 & 3 & 3 & 3 & 3 & 3 & 3 & 3 & -1 & -5 \\
\frac{9}{pL}(E_2-E_{g2})= & -5 & -9 & -5 & -1 & 3 & 3 & 3 & 3 & 3 & 3 & 3 & -1 \\
\frac{9}{pL}(E_3-E_{g3})= & -1 & -5 & -9 & -5 & -1 & 3 & 3 & 3 & 3 & 3 & 3 & 3 \\
\frac{9}{pL}(E_4-E_{g4})= & 3 & -1 & -5 & -9 & -5 & -1 & 3 & 3 & 3 & 3 & 3 & 3 \\
\frac{9}{pL}(E_5-E_{g5})= & 3 & 3 & -1 & -5 & -9 & -5 & -1 & 3 & 3 & 3 & 3 & 3 \\
\frac{9}{pL}(E_6-E_{g6})= & 3 & 3 & 3 & -1 & -5 & -9 & -5 & -1 & 3 & 3 & 3 & 3 \\
\frac{9}{pL}(E_7-E_{g7})= & 3 & 3 & 3 & 3 & -1 & -5 & -9 & -5 & -1 & 3 & 3 & 3 \\
\frac{9}{pL}(E_8-E_{g8})= & 3 & 3 & 3 & 3 & 3 & -1 & -5 & -9 & -5 & -1 & 3 & 3 \\
\frac{9}{pL}(E_9-E_{g9})= & 3 & 3 & 3 & 3 & 3 & 3 & -1 & -5 & -9 & -5 & -1 & 3 \\
\frac{9}{pL}(E_{10}-E_{g10})= & 3 & 3 & 3 & 3 & 3 & 3 & 3 & -1 & -5 & -9 & -5 & -1 \\
\frac{9}{pL}(E_{11}-E_{g11})= & -1 & 3 & 3 & 3 & 3 & 3 & 3 & 3 & -1 & -5 & -9 & -5 \\
\frac{9}{pL}(E_{12}-E_{g12})= & -5 & -1 & 3 & 3 & 3 & 3 & 3 & 3 & 3 & -1 & -5 & -9
\end{array} \tag{28}$$

Neglecting the impedance of the equalizer connections, the coil terminal voltages are related as

$$\begin{aligned}
E_1-E_7&=0\\
E_2-E_8&=0\\
E_3-E_9&=0\\
E_4-E_{10}&=0\\
E_5-E_{11}&=0\\
E_6-E_{12}&=0
\end{aligned} \tag{29}$$

Thus the 12 equations reduce to

$$\frac{9}{4pL}\begin{array}{lrrrrrrrrrrrr}
 & i_1 & i_2 & i_3 & i_4 & i_5 & i_6 & i_7 & i_8 & i_9 & i_{10} & i_{11} & i_{12} \\
E_{g1}-E_{g7}= & -3 & -2 & -1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 & -1 & -2 \\
E_{g2}-E_{g8}= & -2 & -3 & -2 & -1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 & -1 \\
E_{g3}-E_{g9}= & -1 & -2 & -3 & -2 & -1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 \\
E_{g10}-E_{g4}= & 0 & -1 & -2 & -3 & -2 & -1 & 0 & 1 & 2 & 3 & 2 & 1 \\
E_{g11}-E_{g5}= & 1 & 0 & -1 & -2 & -3 & -2 & -1 & 0 & 1 & 2 & 3 & 2 \\
E_{g12}-E_{g6}= & 2 & 1 & 0 & -1 & -2 & -3 & -2 & -1 & 0 & 1 & 2 & 3
\end{array} \tag{30}$$

In the region of θ between $-\pi/6$ and $+\pi/6$, as shown in Figure 7, the net generated voltages in coils 3, 4, 5, 6, 7, and 8 are zero, and because of the uniform air gap

$$E_{g12}=E_{g1}=E_{g2}=-E_{g8}=-E_{g10}=-E_{g11}=E_g \tag{31}$$

Thus equation 30 becomes

$$\frac{9}{4pL}\begin{array}{lrrrrrrrrrrrr}
 & i_1 & i_2 & i_3 & i_4 & i_5 & i_6 & i_7 & i_8 & i_9 & i_{10} & i_{11} & i_{12} \\
-E_g= & -3 & -2 & 1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 & -1 & -2 \\
-E_g= & -2 & -3 & -2 & 1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 & -1 \\
-E_g= & -1 & -2 & -3 & -2 & 1 & 0 & 1 & 2 & 3 & 2 & 1 & 0 \\
-E_g= & 0 & -1 & -2 & -3 & -2 & 1 & 0 & 1 & 2 & 3 & 2 & 1 \\
-E_g= & 1 & 0 & -1 & -2 & -3 & -2 & 1 & 0 & 1 & 2 & 3 & 2 \\
+E_g= & 2 & 1 & 0 & -1 & -2 & -3 & -2 & 1 & 0 & 1 & 2 & 3
\end{array} \tag{32}$$

The equalizer currents are related to the armature currents as follows in equation 33:

$$\begin{aligned}
i_{e1}&=i_1-i_{12}=i_4-i_7\\
i_{e2}&=i_2-i_1=i_7-i_8\\
i_{e3}&=i_3-i_2=i_8-i_9\\
i_{e4}&=i_4-i_3=i_9-i_{10}\\
i_{e5}&=i_5-i_4=i_{10}-i_{11}\\
i_{e6}&=i_6-i_5=i_{11}-i_{12}
\end{aligned} \tag{33}$$

Thus in terms of equalizer currents equations 32 are:

$$\frac{9}{4pL}\begin{array}{lrrrrrrrrrrrr}
 & i_{e1} & i_{e2} & i_{e3} & i_{e4} & i_{e5} & i_{e6} \\
-E_g= & -3 & 3 & 7 & 9 & 9 & 7 \\
-E_g= & -7 & -3 & 3 & 7 & 9 & 9 \\
-E_g= & -9 & -7 & -3 & 3 & 7 & 9 \\
-E_g= & -9 & -9 & -7 & -3 & 3 & 7 \\
-E_g= & -7 & -9 & -9 & -7 & -3 & 3 \\
+E_g= & -3 & -7 & -9 & -9 & -7 & -3
\end{array} \tag{34}$$

These six equations can be solved, giving

$$i_{e1}=-\frac{18}{16pL}E_g$$

$$i_{e2}=i_{e3}=i_{e4}=0$$

$$i_{e5}=\frac{18}{16pL}E_g$$

$$i_{e6}=\frac{18}{16pL}(-2E_g) \tag{35}$$

Substituting these into the relations between armature and equalizer currents, equation 33 and using the additional condition that the average armature current over a complete revolution must be zero, gives the armature currents as

$$i_1=i_2=i_3=i_4=i_7=i_8=i_9=i_{10}=0 \tag{36}$$

$$i_5=-i_{12}=i_{e1}=-\frac{18}{16pL}E_g \tag{37}$$

$$i_6=-i_{11}=i_{e5}=+\frac{18}{16pL}E_g \tag{38}$$

These equations are valid only in the region of θ between $-\pi/6$ and $+\pi/6$ because this is the region for which the generated voltages were written. Thus in any armature coil the rate of change of current as a function of angular position will be as shown in curve H, Figure 8. Integrating this curve gives the armature current as a function of position, curve J.

The peak value is

$$i_{max}=\frac{9E_g}{8L}\times\frac{\pi}{3\omega}=\frac{3\pi E_g}{8\omega L} \tag{39}$$

Because of the limited number of coils these curves do not represent current distribution. When a coil is at $3\pi/2$ it has maximum current, another at $7\pi/2$ has negative maximum, and all others have no current.

To find the armature magnetomotive force we must find E_g and L. The inductance of a coil is determined by the area and effective length of air gap, and the square of the number of turns.

Thus

$$L=\frac{ld\left(\frac{\pi}{4}\right)n^2}{\frac{4}{3}g}=\frac{3\pi ldn^2}{16g} \tag{40}$$

Nomenclature

a = number of armature turns per electrical radian
b = number of equalizer connections per electrical radian
d = armature diameter
E = terminal voltage of one coil of elementary machine
E_g = generated voltage in one coil of elementary machine
g = air gap length
I_e = equalizer current—rms
i = coil current in elementary machine
i_a = current distribution around armature
i_e = equalizer current
i_s = current per segment of armature winding
l = armature length
L = self-inductance of one coil in elementary machine
m_a = magnitude of armature magnetomotive force
m_f = unbalanced excitation on one pole in ampere turns
n = number of armature turns per segment
P = number of poles
p = operator d/dt
S_c = number of bars in the commutator
t = time—seconds
$\alpha = \pi P/2S_c$
θ = angle with respect to center line of main pole (mechanical radians)
ω = angular armature speed—radians per second (electrical)

The generated voltage depends on the excitation, effective air gap, and the length and speed of conductors.

Thus

$$E_g = \frac{4}{3}\frac{m_f nl}{\frac{4}{3}g} \times \frac{\omega d}{4} = \frac{m_f l d n \omega}{4g} \tag{41}$$

Substituting these into i_{max} gives

$$i_{max} = \frac{3\pi}{8\omega} \times \frac{m_f l d n \omega}{3\pi l d n^2} \times \frac{16g}{4g} \tag{42}$$

$$\frac{m_f}{2n}$$

Thus the armature magnetomotive force when the currents are maximum is

$$n i_{max} = \frac{m_f}{2} \tag{43}$$

exactly half of the applied excitation, and in a direction to oppose the applied magnetomotive force. At another time, such as that shown in Figure 7, the current in coils 11 and 12 will be half of the maximum value, again giving a maximum armature magnetomotive force of half of the applied excitation.

Now let us go back and find the rms value of the equalizer currents. From equation 35 we see that the rate of change of equalizer currents as a function of position is as shown in curve K. Thus integrating gives currents as shown in curve L. The maximum value of this curve is the same as the maximum armature current, that is

$$i_{e(max)} = \frac{m_f}{2n} \tag{44}$$

The rms value of this wave shape is

$$I_e = \frac{m_f}{2n\sqrt{6}} \tag{45}$$

If there is one turn per coil, $n = 1$ and

$$I_e = \frac{m_f}{2\sqrt{6}} = 0.204\ m_f \tag{46}$$

If, as a check, we apply equation 20 developed from the test results to this case we have

$$a = b = \frac{3}{\pi}$$

$$I_e = \frac{m_f}{2\pi ab} = \frac{m_f \pi}{18} = 0.174\ m_f \tag{47}$$

This is a good check considering the entirely different assumptions which were made.

Discussion

Paul W. Franklin (Bendix Aviation Corporation, Teterboro, N. J.): The mathematical treatment of equalizer currents, as given in the paper is very similar to the approximate calculation of synchronous machinery damper winding currents. If we hold a d-c armature stationary, but rotate the stator and the brush gear, passing a current through the brushes, we obtain similar conditions, namely—an armature magnetomotive force (mmf) relatively stationary to the pole wheel. The equalizers superpose a bodily incorporated damper winding upon the normal armature winding, which is short circuited. Since, however, the coil pitch of the new damper winding is equal to double pole pitch, it will be effective only upon subharmonics, that is, harmonics whose integer is below the number of pole pairs, if the first harmonic is assigned to the armature circumference.

The general theory of equalizers could then proceed as follows: Given an irregular stator shunt field mmf, reduced to equal air-gap reluctance (that is, equal shunt coil mmf but unequal air-gap would appear as equal gap but different shunt mmf) said distribution is to be analyzed and the resulting subharmonic mmf's have to be compensated by the equalizer winding. Or, as the authors have done, the mmf of the equalizer winding—now of the nature of a special squirrel cage winding—is equal to the subharmonics, and from this the currents may be computed. This would permit the calculation of currents for moderate unsymmetries, assuming, that the tired and by that time disgusted designer wishes to go so far.

It now would be of interest to speculate upon the influence of resistance and reactance in the equalizers. It should be noted that the equalizing currents caused by differences in pole flux go axially through the armature, whereas equalizing currents, caused by variable brush contact do not enter the armature, if the equalizers are fastened to the commutator. In the first case, a damping factor could be calculated, similar to the treatment published by Richter[1] in 1930, who also states that the equalizer currents are almost 90 degrees out of phase with their voltages. Due to reactance and resistance, the actual equalizer currents will be smaller than resulting by above calculation and this may be the reason why the actual measured rms value of the current was smaller than the sum of the calculated harmonics. There is no doubt, however, that such a refinement is not necessary for ordinary design calculations.

There is, however, one point of interest which should be discussed in connection with this paper. It is generally known that a well equalized lap winding is the best suited for difficult commutation conditions. It has been the experience of friends of the writer, that aircraft generators with well equalized lap windings are occasionally inferior to normal wave windings with regard to commutation. Aircraft generators are characterized by high temperatures, high speeds, high magnetic densities and high electromagnetic loading (ampere conductors per inch).

Whereas equalization for uneven pole flux takes place essentially at pole frequency, equalization for independent voltage polygons takes place at commutator bar frequency, which is at least ten times higher than the pole frequency. It is quite possible that the time constant of the equalizer connection at the high speeds of aircraft machines approaches the magnitude of the time of the commutator bar cycle. In addition to this, increased brush vibration, again at commutator bar frequency, and the ensuing additional need for corrective action from the side of the equalizers, may form a partial explanation for the occasional failure of lap windings in aircraft generators.

The writer wishes to congratulate the authors for their excellent paper, which, to the writer's knowledge, is the first published mathematical treatment of equalizer current.

science of d-c machine design. The accuracy with which one can calculate the equalizer current by the formulas presented will determine the true value of these results. The assumptions made in the analysis seem reasonable. However, as stated by the authors, the results are substantiated only by comparison with test of one machine.

In a survey of the d-c machines built by the Large Motor and Generator Engineering Division of the General Electric Company, the only data found that is useful to check the calculations of this paper are that resulting from accident or failure. Obviously, exact numerical results were never taken. Equation 5 of this paper was applied to a number of machines, and the following calculated values of Table I of the discussion were obtained.

The exciter, Item 1 of Table I, had been received in test with one pole reversed. As rated voltage was approached in taking the saturation curve data, the armature smoked severely. The examination of the armature revealed that the equalizer insulation was completely destroyed. The calculated current density would indicate that such results could be expected on a normal equalizer winding which has a very poor heat dissipating ability.

The machine, Item 2 of the table, was a marine propulsion motor. This motor was tested under simulated damaged condition with one field coil removed. It was operated with rated field current and load. The calculated current density for this mode of operation is 417 amperes per square inch. This motor operated with no apparent signs of excessive heating.

The other three items in Table I were calculated for comparison. These machines have never been operated without a field coil excited or with one reversed. However, there have been reports from various mill operators who have operated generators similar to these with one field coil removed from the circuit for extended periods of time with no apparent damage to the equalizer winding. The values given in Table 1 of the discussion, Items 3, 4 and 5 confirm such observations.

In conclusion, this tidbit of evidence supports the results of this paper and makes them seem reasonable. However, further tests on a variety of designs are needed to fully prove its limitations and accuracy.

T. M. Linville and **D. P. Strang:** Mr. Franklin has pointed out correctly the similarity between the flow of currents in a d-c machine armature and the current flow in the amortisseur winding of a synchronous machine. The method of the paper was based upon the presumption that reactance determined the magnitude of the current in the equalizer connections and that resistance was negligible. Speculation on this point as suggested by Mr. Franklin is important. The authors feel that their assumption has been well substantiated by actual experience with d-c machines and by the behavior of similar transient currents in a-c machines. However, more test data showing the flow of equalizer currents is needed and we hope that some of this and further extension of the method for calculation will be done in the colleges. It is a well-known fact that equalizer connections are necessary for the successful operation of all d-c machines except the small ones which can be built with no more than two circuits in the armature winding. Mr. Franklin has pointed out how important it is to know the relative advantages of an equalized lap winding in comparison with a two circuit wave winding for aircraft generators. These matters are of major concern, not only to designers, but to users who depend upon good performance of d-c motors and generators.

We are interested in experiences that motor manufacturers may have had during factory tests when field coils may have accidentally been connected with the wrong polarity. This places an unusual load upon the equalizer connections showing up in overheating. In this connection we are grateful to Mr. Smith for the example cited. He has also given some calculations, based on the paper, showing the current density in the equalizer connections of actual machines when one field coil is reversed. Figures are given for normal field current and also for field current necessary to obtain rated voltage. These figures illustrate the fact that the load on the equalizers is greater the fewer the number of poles.

In the oral discussion, P. L. Alger proposed that the factor δ be calculated by the following relation:

$$\delta = \frac{1}{2P}\sqrt{\frac{P^4-4}{3}}$$

Such a simplification will be helpful. He noted that harmonics in the no-load air gap flux wave higher than the third harmonic were neglected and asked about the influence of including the higher harmonics. Within the limits of our knowledge, it appears that the inclusion of harmonics above the third result only in unnecessary complication for all except the very exceptional machine. We think that the higher harmonics have greater importance in a small machine, such as the aircraft starter used for test results given in the paper. In an industrial motor or generator, the higher harmonics should be of less importance. Mr. Alger pointed out that the reactance of the equalizer connection should be low and we agree that this reactance should be no more than 10 per cent of the slot leakage reactance of a single armature coil. This might be a desirable rule-of-thumb for the maximum value.

A question was raised about the relative merits of a 4-pole armature winding, fully equalized, with single versus double reentrancy. We stated that single reentrancy might be preferable. It must be pointed out, however, that the singly reentrant winding in such a case may result in the flow of equalizer current of higher harmonics, such as at slot frequency. This may result in higher losses such as an increase in the apparent no load core loss. The doubly re-entrant winding may be free of these losses and be entirely satisfactory. The answer to the question should be determined by a calculation of the voltage difference between points which are to be connected by equalizers in the case of each winding under consideration.

We appreciate the mention of B. G. Lamme's work cited by C. G. Veinott.

M. A. Baker asked how the formulas should be modified in case one equalizer connection was used for every other commutator segment rather than an equalizer connection for every segment. In such a case the results given by the paper would need to be doubled. Similarly, if only one-third of the full number of equalizer connections were used, the current calculated by the paper would need to be tripled. This can be seen if the analysis of the paper is considered in terms of increasing the angle α to make it equal to the angle between two adjacent equalizer connections. In case this angle becomes so large that sine α is no longer equal to α (as is necessary if the simple result of the paper is to be valid) equation 3 must be used in place of equation 5.

PAUL B. ROBINSON
ASSOCIATE AIEE

A PREVIOUS paper[1] discusses the importance of being able to predetermine the transient characteristics of d-c rotating machines, and its lists the papers of several investigators[2,3,4] who have advanced methods for such predetermination. Reference 1 of this paper presents typical d-c machine values for one of the parameters required by the methods of references 2, 3, and 4, namely r_a', the per-unit equivalent resistance. These values were determined by means of the theories[3,4] and were furnished by several manufacturers to the D-C Machinery Subcommittee of the AIEE Rotating Machinery Committee for presentation in reference 1, in which paper it was promised that "as progress is made in the determination of inductances, it is expected that similar analysis and confirmation by test will be forthcoming."

The present paper is a step toward the fulfillment of that promise. Methods will be described for obtaining the inductance by test and for calculating the inductance from design data. Some typical values obtained by these methods will be given, and it is hoped that other investigators will be inspired to use the methods to obtain values of inductance which can then be assembled and presented in a paper which will parallel reference 1. It also is hoped that suggestions will be made toward improving the methods both for test and for calculation.

A-C Impedance Test

The armature circuit inductance may be determined as described in the footnote to Table I of reference 4. This involves the measurement of the a-c impedance between line terminals of the stationary d-c machine by impressing an a-c voltage on these terminals and measuring the resulting alternating current. All brushes are lifted, and copper jumpers of suitable section to carry the expected current are connected between each brush stud and all the commutator leads of the bars which would normally be short circuited by the brushes of that particular stud. This eliminates the brush and brush contact resistance during the test.

For obtaining unsaturated values of inductance, the shunt field winding is left unexcited, either open- or short-circuited, and several readings are taken of a-c volts and a-c amperes with constant line frequency so that a curve of volts versus amperes can be plotted. Usually a curve extending to a current of about one half of the rated line current of the machine will be sufficient to give good results. The slope of this curve is the a-c impedance of the circuit, and if there is any departure from a straight line due to saturation at the higher voltages, the slope of the curve near the origin represents the unsaturated impedance.

For obtaining relatively saturated values of inductance the procedure just described should be repeated with rated d-c field current maintained in the shunt winding.

The principal interest in determining the inductance is to obtain the armature circuit decrement factor σ_a and hence the maximum rate of rise of short-circuit current, equation 3, reference 3. Therefore the transient impedance is desired, and any series windings on compound wound machines should preferably be omitted when conducting the foregoing tests, particularly if the shunt field winding is open circuited. Furthermore, this omission eliminates the tendency to rotate as a series motor.

Experience has shown no perceptible difference in the inductance values obtained by using a-c frequencies ranging from 25 to 60 cycles, and therefore it is suggested that the more convenient frequency, 60 cycles, be used. If this is done it will usually be found that the a-c impedance of the armature circuit may be assumed to be entirely reactance although precautions should be taken to verify this by measuring the resistance of the circuit as tested to see that it is negligible. For a 60-cycle test the per-unit inductance l_a' or the per-unit saturated inductance l_{as}' may be determined from the appropriate test curve as

$$l_a' \text{ (or } l_{as}') = \frac{\text{slope of curve}}{377} \times \frac{I_{a1} \times N_1 \times P}{19.1\, V_1}$$

in which I_{a1} is the rated full-load armature amperes; V_1, the rated armature voltage; N_1, the rated base speed in revolutions per minute; and P, the number of poles. The per-unit inductance l_a' (or l_{as}') is identical with the inductance coefficient C_a referred to in references 3 and 4.

D-C Build-Up Method

Another test method of determining the armature circuit inductance is to measure oscillographically the rate of rise of direct current after sudden application of a low d-c voltage to the terminals of the d-c machine. For this type of test the brush jumpers should be used as in the a-c impedance test; the shunt field should be excited or not depending on whether saturated or unsaturated inductances are desired; and in addition the rotor should be firmly blocked to prevent rotation. The voltage source should be a low-volt-

Paper 50-193, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 5, 1950; made available for printing August 18, 1950.

H. D. Snively and Paul B. Robinson are both with the General Electric Company, Schenectady, N. Y.

The authors wish to thank T. M. Linville for contributions to the Appendix of this paper and to V. C. Strode and W. C. Bachtel for assistance in obtaining test and calculated data.

Figure 1. Outline of armature slot showing flux paths

Figure 3. Idealized magnetization curve of pole piece steel

age high-current low-inductance supply capable of maintaining reasonably constant voltage at the machine terminals. The inductance in henrys of the armature circuit can be calculated as the applied terminal voltage divided by the initial rate of rise of current in amperes per second. This inductance multiplied by $(I_{a1}N_1P/19.1\,V_1)$ is the per-unit inductance l_a' (or l_{as}'). Several readings should be taken at different applied voltages resulting in line currents from about 10 per cent up to 50 per cent rated. Care should be exercised not to maintain the current any longer than necessary to obtain the desired data. Terminal resistance should be measured as before so that several points on the build-up curve can be checked in addition to the zero time point.

Due to the somewhat more complicated test set-up and calculations required as well as the need for a stiff voltage source, the d-c build-up method is not as convenient or as cheap as the a-c impedance method. When tests have been made by both methods on the same machine, there has been no indication that either method gives superior results, and hence the a-c impedance test is being used more often than the other method at the present time.

Calculation of Inductance

The calculation of the armature circuit inductance from design data involves the calculation and summation of the inductances associated with each of the various permeance paths of the quadrature axis windings. The series windings are not included for the reasons given previously. The formulas for the various inductances are derived in the Appendix and will not be repeated here. The total inductance calculated from these expressions is in henrys and can be converted to per-unit by multiplying by the factor $(I_{a1}N_1P/19.1\,V_1)$.

It is suggested that these formulas be arranged systematically on a suitable calculation form sheet by anyone who plans to use the method to calculate inductances of a large number of machines.

Comparison of Tests and Calculations

A 900-kw 720-rpm 300-volt 8-pole 40-degree open generator without pole face winding was tested by the a-c impedance method, and the results showed an l_a' of 0.82 with unexcited field and an l_{as}' of 0.371 with excited field. The calculated value of per-unit inductance is based on no saturation and in this case equalled 0.88 which is 7 per cent higher than the test value.

Figure 2. Outline of pole face slot

A 200-kw 3,600-rpm 250-volt 4-pole 40-degree semienclosed generator without pole face winding showed an l_{as}' of 0.42 with excited field. No test was made for unsaturated inductance but calculations gave 0.47 which is not as much higher than l_{as}' as was the previous example.

A 1,500-horsepower 575-rpm 500-volt 8-pole 40-degree open, forced ventilated motor with pole face winding gave an l_a' of 0.15 with unexcited field by the a-c method and 0.16 by the d-c build-up method. For l_{as}' with excited field the results were 0.14 by both methods. The calculated value for l_a' was 0.155.

A 1,500-kw 720-rpm 500-volt 8-pole 40-degree open generator with pole face winding gave an l_a' of 0.26 with unexcited field, while the calculated value was 0.20. The test value of the saturated inductance was not obtained.

A 750-kw 720-rpm 250-volt 6-pole 40-degree open generator with pole face winding gave a test value for l_{as}' of 0.15 with excited field. No test was made for unsaturated inductance. Calculations showed 0.27 for l_a'.

The foregoing data, as well as other results not recorded here, indicate that the method of calculation is reasonably accurate, giving results sometimes higher and sometimes lower than test values for unsaturated inductance. It is the belief of the authors however, that on the average the calculated values are somewhat lower than the tested values.

The data also indicate that the suggested values for C_z in references 3 and 4 of 0.6 for machines without pole face windings and 0.15 for machines with pole face windings, are fairly good approximate figures to use if no better information is

available concerning the machine being considered.

The data indicates that saturation of the direct axis has a more pronounced effect on the machines without pole face windings than it has on the other type. This is to be expected because the better compensation in the main pole space definitely minimizes the flux produced by quadrature axis windings in the main pole permeance paths.

Appendix. Machine Inductance Calculations

The problem of computing the inductance of a d-c machine has been approached from the concept of flux linkages about one electrical path. It is well known that the inductance of a circuit is equal to the flux linkages about it divided by the current in it, and this theorem can be applied to one parallel path in a d-c machine. The total inductance of the machine will be the inductance of one path divided by the number of parallel paths. Thus, the problem is resolved to one of finding the flux linkages about one path of the machine.

The problem is simplified even more by observing that there are many magnetic circuits within the machine which may be treated independently, provided it is assumed that the steel does not saturate. Thus, the various self and mutual inductances within an electrical path can be determined by themselves, then added to get the total inductance of the path.

Because of the symmetry of the machine, all paths are assumed to have equal currents. With this, and the assumption that the steel has infinite permeability, the total magnetomotive force around a particular magnetic circuit can be determined. The magnetomotive force drop will fall entirely across the air paths of the magnetic circuit, and if the permeance of the path can be determined, the total flux can be evaluated. Multiplying this flux by the turns linked in one electrical path gives the flux linkages in that circuit.

The process of calculating inductance, then, follows these steps:

1. Determine the total magnetomotive force existing in the magnetic circuit of interest that affects one electric circuit.
2. Determine the permeance of the magnetic circuit, and multiply by the magnetomotive force, thereby obtaining total flux in the magnetic circuit which affects one electric circuit.
3. Multiply this flux by the number of turns it links in the one electric circuit. This, now, gives the total flux linkages about that electric circuit.
4. Divide these linkages by the current in that one electric circuit to get its inductance.
5. Divide this inductance by the number of paths in parallel to obtain the inductance of the whole machine.

Armature Conductor Leakage Reactance

Consider the leakage reactance of armature conductors embedded in a slot. The magnetomotive force around path A is simply $4\pi/10$ times the total slot current, I_aZ/s. The permeance around path A is Ld_3/w_1. Thus, the flux per slot around path A is, in Figure 1

$$\phi_A = \frac{4\pi}{10}\frac{Z}{s}I_a\frac{Ld_3}{w_1} \tag{1}$$

This flux links all conductors in the slot so that the linkages are

$$\Psi = \frac{4\pi Z^2 L d_3 I_a}{10 s^2 w_1} \tag{2}$$

For path C, the permeance is d_2L/w_1, and since flux is produced by only half the current

$$\phi_C = \frac{4\pi}{10}\frac{ZIa}{2s}\frac{Ld_2}{w_1} \tag{3}$$

This links half the current in the slot, so that the flux linkages are

Figure 4. Variation of pole face winding leakage inductance with load current

$$\Psi_C = \frac{4\pi}{10}\frac{Z^2 L d_2 I_a}{4 s^2 w_1} \tag{4}$$

In paths B and D, the magnetomotive force is linear in distance, and the linkages will be parabolic. The average value will be one-third the maximum linkages, because of the parabolic shape. Thus

$$\Psi B,D = \frac{4\pi}{10}\frac{Z^2 L(d_1-d_3)I_a}{3 s^2 w_1} \tag{5}$$

The total of these linkages is

$$\Psi s = \frac{4\pi}{10}\frac{Z^2}{s^2}\frac{L}{w_1}I_a\left(d_2+\frac{d_3}{4}+\frac{d_1-d_3}{3}\right) \tag{6}$$

which is the total linkage per slot. In one parallel circuit, there are s/a_a slots in series, so that the total linkages per circuit may be calculated by

$$\Psi w = \frac{4\pi}{10}\frac{Z^2}{s a_a}\frac{L}{w_1}I_a\left(d_2+\frac{d_3}{4}+\frac{d_1-d_3}{3}\right) \tag{7}$$

The inductance of the circuit is simply $\Psi_w 10^{-8}/I_a$, and the inductance of the a_a parallel circuits is $\Psi_w 10^{-8}/I_a a_a$.

$$X_{al} = \frac{4\pi}{10^8}\frac{Z^2}{s a_a^2}\frac{L}{w_1}\left(\frac{12d_2+4d_1-d_3}{12}\right) \tag{8}$$

For inch units, this must be multiplied by 2.54. Also since d_3 will be quite small with respect to $12d_2$ and $4d_1$, it can be neglected. Thus

$$X_{al} = \frac{31.9}{10^8}\frac{Z^2 L}{s a_a^2 w_1}\left(d_2+\frac{d_1}{3}\right) \text{ henrys} \tag{9}$$

Nomenclature

a_a = number of parallel paths in armature
a_b = number of parallel paths in pole face winding
a_c = number of parallel paths in commutating pole winding
d_0 = depth of pole face slot opening, inches
d_1 = total depth of armature copper in slot, inches
d_2 = depth from top of armature tooth to top of copper, inches
d_3 = separation between top and bottom armature conductors
d_4 = depth of pole face bar, inches
h_p = height of pole punching, inches
l_b = length of pole face bars, inches
n_b = total number of pole face bars
p_a = main pole arc, inches
p_p = pole pitch, inches
s = total number of armature slots
t_c = width of commutating pole tip, inches
w_0 = width of pole face slot opening, inches
w_1 = armature slot width, inches
w_2 = average width of pole face slot, inches
w_c = width of commutating pole body, inches
w_s = width of stator end connection strips, inches
B = width of main pole body, inches
B_i = intrinsic induction of main pole steel, lines/inches^2
B_n = flux density of steel at knee of saturation curve
D = armature diameter, inches
E = height of commutating pole winding, inches
F = height of main pole at tip, inches
G = average main pole gap, inches
G_{max} = maximum main pole gap, inches
H = width of pole shoe, inches
I = rated machine current, amperes
I_a = armature current in one parallel path, amperes
I_b = pole face winding current in parallel path, amperes
I_c = commutating pole current in parallel path, amperes
I_{ss} = current in equivalent conductor, stator, end connections, amperes
K_{dm} = distribution factor of end windings
L = stacked length of rotor iron, inches
P = number of poles
T = number of turns on each commutating pole
X_{al} = armature slot leakage inductance, henrys
X_{bl} = pole face slot leakage inductance, henrys
X_{cl} = commutating pole leakage inductance, henrys
X_G = inductance due to flux under main pole, henrys
X_g = inductance due to flux under commutating pole, henrys
X_{end} = armature end turn inductance, henrys
X_{hend} = stator end connection inductance, henrys
Z = total number of armature conductors
ϕ = angle between armature end turns and core
μ = permeability of steel below saturation—gausses/oersted
Ψ = flux linkage

Figure 5 (above). Outline of poles and armature for determining inductance due to flux under main and commutating poles

Figure 6 (right). Outline of poles and armature for determining leakage inductance of commutating pole

Pole Face Bar Leakage

A similar process is used to determine the leakage inductance of the pole face bars. See Figure 2.

Across the gap, the flux linkages are

$$\Psi_A = \frac{4\pi}{10} I_b \frac{d_a L}{w_b}$$

In the slot proper, the same parabolic distribution will occur as in the armature slots, so that

$$\Psi_B = \frac{4\pi}{10} I_b \frac{d_s L}{3w_s} \tag{10}$$

The total linkages per slot are

$$\Psi = \frac{4\pi}{10} I_b L \left(\frac{d_s}{3w_s} + \frac{d_a}{w_b} \right) \tag{11}$$

There are n_b/a_b slots per series circuit, so that the linkages per circuit are

$$\Psi = \frac{4\pi}{10} \frac{I_b n_b L}{a_b} \left(\frac{d_s}{3w_s} + \frac{d_a}{w_b} \right) \tag{12}$$

Dividing this by circuit current I_b and by the number of parallel circuits to get total machine inductances gives

$$X_{bl} = \frac{4\pi}{10^8} \frac{n_b L}{a_b^2} \left(\frac{d_s}{3w_s} + \frac{d_a}{w_b} \right) \tag{13}$$

With inch units

$$X_{bl} = \frac{31.9}{10^9} \frac{n_b L}{a_b^2} \left(\frac{d_s}{3w_s} + \frac{d_a}{w_b} \right) \text{ henrys} \tag{14}$$

If the slot is not open, as is sometimes the case at the edge of a main pole, saturation cannot be neglected around the bar. Assume, however, that saturation occurs in the steel only where the gap would normally be. This being the case, the flux in the saturated steel may be divided into two components: the flux intrinsic with the steel, B_i; and the flux that would exist in spite of the steel, B_a. The B_a, or air flux, is obviously proportional to magnetomotive force. The intrinsic flux, B_i, is a constant once the steel has saturated. The sum of the two gives the well known gently rising characteristic of the flux-density field-intensity curve of steel above its knee.

Thus, the linkage around path A will be, after saturation

$$\Psi_A = \frac{4\pi}{10} I_b \frac{d_a L}{w_b} + B_i d_a L \tag{15}$$

Adding to it the unchanged linkages through the conductor, the total linkages per slot are

$$\Psi = \frac{4\pi}{10} L I_b \left(\frac{d_a}{w_b} + \frac{d_s}{3w_s} \right) + B_i d_a L \tag{16}$$

The total inductance is found as before and is

$$X_{bl} = \frac{31.9 n_b L}{10^9 a_b^2} \left(\frac{d_a}{w_b} + \frac{d_s}{3w_s} \right) + \frac{B_i d_a L n_b}{10^8 I a_b} \text{ henrys} \tag{17}$$

The value of B_i is taken from the flux-density field-intensity curve of the steel, idealized as shown in Figure 3.

Equation 17 is valid only in the saturated region, or when

$$B_i + \frac{4\pi I}{10 w_b a_b} > B_n \tag{18}$$

Below saturation, the expression is modified as follows:

$$X_{bl} = \frac{31.9 n_b L}{10^9 a_b^2} \left(\frac{\mu d_a}{w_b} + \frac{d_s}{3w_s} \right) \tag{19}$$

where $\mu = B_n/H_n$. This equation is valid when

$$B_i + \frac{4\pi I}{10 w_b a_b} < B_n \tag{20}$$

Note in equation 17 that the inductance is a function of machine current. This is to be expected of a nonlinear circuit such as this. With this, and the linear region, a curve of inductance versus current is obtained as in Figure 4.

Needless to say, care must be exercised in deciding which value of inductance to use.

Main Pole Flux Inductance

The next component of inductance to be determined will be that due to armature flux crossing the gap to the main pole. See Figure 5.

The magnetomotive force existing across the gap can be simply expressed in terms of a peripheral distance x from the center of the main pole and the various parameters of the machine, if it is assumed that the armature has a large number of conductors. With this assumption, the current may be considered to flow in a sheet along the armature surface. Considering the conductors in the region $0 < x < \pi D/P$ to be one side of a coil, and those from $\pi D/2P < x < \pi D/P$ to be the other half, the maximum number of turns at $x = \pi D/2P$, with a maximum magnetomotive force of

$$M = \frac{4\pi}{10} \frac{Z}{2P} I_a \tag{21}$$

This magnetomotive force is graded to zero at $x = 0$, so that in the region $0 < x < \pi D/2P$

$$M = \frac{4\pi}{10} \frac{Z x I_a}{\pi D}$$

$$= \frac{4 Z I_a x}{10 D} \tag{22}$$

From $x = 0$ to $x = p_a/2$, the permeance of a differential distance dx is $L dx/G$. Thus, the differential flux is

$$d\phi = \frac{4 Z L I_a x dx}{10 G D} \tag{23}$$

The same magnetomotive forces and fluxes appear under each pole, so that it will be correct to treat the linked conductors of one circuit as if they were all under one pole, provided they are still considered as if in series. Thus the total turns linked will be $Z/2a_a$, and grading this to zero at $x = 0$

$$N = \frac{Z}{2a_a} \frac{2Px}{\pi D}$$

$$= \frac{ZPx}{\pi a_a D} \tag{24}$$

The differential linkage is then

$$d\Psi=\frac{4Z^2LI_aPx^2dx}{10\pi Ga_aD^3} \tag{25}$$

Except for fringing at the pole tips, equation 25 should be integrated from $x=0$ to $x=p_a/2$ and doubled (to get linkages on both sides of the pole). Flux plots have shown, however, that the fringing effect can be included by using $^1/_4(p_a+2G)$ instead of $^1/_2p_a$. This integration is performed as follows

$$\Psi=2\int_0^{^1/_4(p_a+2G)}\frac{4Z^2LI_aPx^2dx}{10\pi Ga_aD^3}$$

$$=\frac{Z^2LI_aP(p_a+2G)^3}{3\ 10\pi Ga_aD^3} \tag{26}$$

The inductance of the whole machine is

$$X_{aG}=\frac{Z^2LP(p_a+2G)^3}{3\ 10^9\pi GD^2a_a^2} \tag{27}$$

But $(\pi D/p)^2=p_p^2$, and multiplying through by $(\pi D/Pp_p)^2$ gives

$$X_{aG}=\frac{\pi Z^2L(p_a+2G)^3}{3\ 10^9GPa_a^2p_p^2} \tag{28}$$

Or, in inch units

$$X_{aG}=\frac{2.66Z^2L(p_a+2G)^3}{10^9GPa_a^2p_p^2}\text{ henrys} \tag{29}$$

The next component of inductance to be determined is that due to flux from the pole face windings that crosses the main gap. Here again it will be assumed that the magnetomotive force is linearly distributed along the face of the main pole. This is not nearly so good an assumption for the pole face windings as for the armature, but at least the depth of the pole face slots tends to smooth out the steps in the magnetomotive force curve.

The same process is used for the pole face windings as for the armature.

$$M=\frac{4\pi n_bI_bx}{10P(p_a+2g)} \tag{30}$$

$$d\phi=\frac{4\pi n_bI_bLxdx}{10P(p_a+2G)G} \tag{31}$$

$$d\Psi=\frac{4\pi n_bLI_bxn_b2xdx}{10P(p_a+2G)G2a_b(p_a+2G)}$$

$$=\frac{4\pi n_b^2LI_bx^2dx}{10PG(p_a+2G)^2a_b} \tag{32}$$

$$\Psi=2\int_0^{^1/_4(p_a+2G)}\frac{4\pi n_b^2LI_bx^2dx}{10PG(p_a+2G)^2a_b}$$

$$=\frac{\pi n_b^2LI_b(p_a+2G)}{3\ 10PGa_b} \tag{33}$$

$$X_{bG}=\frac{\pi n_b^2L(p_a+2G)}{3\ 10^9PGa_b^2} \tag{34}$$

In inch units

$$X_{bG}=\frac{2.66n_b^2L(p_a+2G)}{10^9PGa_b^2}\text{ henrys} \tag{35}$$

The next component will be the mutual inductance between the armature and the pole face windings.

$$M=\frac{4\pi n_bI_bx}{10P(p_a+2G)} \tag{30}$$

$$d\phi=\frac{4\pi n_bI_bLxdx}{10P(p_a+2G)G} \tag{31}$$

The turns linked in the armature are

$$N=\frac{ZPx}{\pi a_aD} \tag{24}$$

so that

$$d\Psi=\frac{4n_bZI_bLx^2dx}{10(p_a+2G)Ga_aD} \tag{36}$$

$$\Psi=2\int_0^{^1/_4(p_a+2G)}\frac{4n_bZI_bLx^2dx}{10GDa_a(p_a+2G)}$$

$$=\frac{n_bZI_bL(p_a+2G)^2}{3\ 10GDa_a} \tag{37}$$

$$X_{abG}=\frac{n_bZL(p_a+2G)^2}{3\ 10^9GDa_aa_b} \tag{38}$$

Multiplying through by $\pi D/Pp_p$, and converting to inch units, gives

$$X_{abG}=\frac{2.66n_bZ(p_a+2G)^2}{10^9GPp_pa_aa_b}\text{ henrys} \tag{39}$$

The sum of the three main gap inductances can be written as follows

$$X_G=X_{aG}-2X_{abG}+X_{bG} \tag{40}$$

The negative sign appears because of the manner of connection between armature and pole face circuits. Inserting equations 29, 35, and 39 into 40, gives

$$X_G=\frac{2.66L(p_a+2G)}{10^9PG}\left(\frac{Z(p_a+2G)}{a_ap_p}-\frac{n_b}{a_b}\right)^2 \tag{41}$$

This equation takes care of all flux under the main pole. Next, one will be derived to account for flux under the commutating pole.

Commutating Pole Flux Inductance

First, that due to armature magnetomotive force. Because of the narrow width of the commutating pole, sufficient accuracy will be obtained by assuming a uniform magnetomotive force under it.

$$M=\frac{4\pi}{10}\frac{Z}{2P}I_a \tag{42}$$

$$\phi=\frac{4\pi}{10}\frac{ZI_a}{2P}\frac{(t_c+2.5g)L}{g} \tag{43}$$

The 2.5g term accounts for fringing, and is based on flux plots.

$$\Psi=\frac{4\pi}{10}\frac{ZI_aL(t_c+2.5g)Z}{2P_g\ \ 2a_a} \tag{44}$$

$$X_{ag}=\frac{\pi Z^2L(t_c+2.5g)}{10Pga_a^2} \tag{45}$$

Or, in inch units

$$X_{ag}=\frac{31.9Z^2L(t_c+2.5g)}{4\ 10^9Pga_a^2} \tag{46}$$

For the pole face windings

$$M=\frac{4\pi}{10}\frac{n_bI_b}{2P} \tag{47}$$

$$\phi=\frac{4\pi}{10}\frac{n_bI_b}{2P}\frac{(t_c+2.5g)L}{g} \tag{48}$$

$$\Psi=\frac{4\pi n_bI_b(t_c+2.5g)L}{10\ 2P\ \ g}\frac{n_b}{2a_b} \tag{49}$$

$$X_{bg}=\frac{\pi n_b^2L(t_c+2.5g)}{10^9Pga_b^2} \tag{50}$$

In inch units

$$X_{bg}=\frac{31.9n_b^2L(t_c+2.5g)}{4\ 10^9Pga_b^2}\text{ henrys} \tag{51}$$

and for the commutating pole

$$M=\frac{4\pi}{10}TI_c \tag{52}$$

$$\phi=\frac{4\pi}{10}TI_c\frac{(t_c+2.5g)L}{g} \tag{53}$$

$$\Psi=\frac{4\pi TI_c(t_c+2.5g)LPT}{10g\ \ a_c} \tag{54}$$

$$X_{cg}=\frac{4\pi T^2PL(t_c+2.5g)}{10^9ga_c^2} \tag{55}$$

In inch units

$$X_{cg}=\frac{31.9T^2PL(t_c+2.5g)}{10^9ga_c^2}\text{ henrys} \tag{56}$$

Just as the self- and mutual-inductances combined into a perfect square for the main pole, they combine into a perfect square for the commutating pole. Therefore, without bothering to derive all the mutual inductances (which can be done easily), the expression for inductance due to commutating pole flux can be written as

$$X_g=\frac{31.9(t_c+2.5g)LP}{10^9g}\times\left(\frac{T}{a_c}+\frac{n_b}{2a_bP}-\frac{Z}{2a_aP}\right)^2 \tag{57}$$

Commutating Pole Leakage Inductance

A very real amount of flux leaks from the commutating pole over to the main pole, and this will represent inductance.

The leakage flux can be divided into two components: that which goes to the tip of the main pole; and that which leaks to the body. Consider first the pole tip components. See Figure 6.

Flux plots show that the flux leaking to the main pole tip comes from near the tip of the commutating pole. This being the case, it will be assumed that the flux links all the turns on the commutating pole.

$$M=\frac{4\pi}{10}TI_c \tag{52}$$

The permeance on one side of the pole tip is given approximately by the following expression

$$P_{cit}=\frac{LF}{\frac{1}{2}\left(p_p-\frac{(p_a+B+2H)}{2}-t_c\right)}$$

$$=\frac{4LF}{2p_p-p_a-B-2H-2t_c} \tag{58}$$

This assumes the region to be a rectangular solid.

The flux on one side of the commutating pole is then

$$\phi_{clt}=\frac{16\pi TI_eLF}{10(2p_p-p_a-B-2H-2t_c)} \tag{59}$$

The total linkages per pole are

$$\Psi_{clt}=2\frac{16\pi T^2I_eLF}{10(2p_p-p_a-B-2H-2t_c)} \tag{60}$$

Since there are P/a_c poles in one series circuit, the total inductance may be written as

$$X_{clt}=\frac{32\pi T^2LFP}{10^9(2p_p-p_a-B-2H-2t_c)a_c^2} \tag{61}$$

Changing to inch units

$$X_{clt}=\frac{255T^2LFP}{10^8a_c^2(2p_p-p_a-B-2H-2t_c)}\text{ henrys} \tag{62}$$

The flux that leaks to the main pole body emanates from along the commutating pole winding. Flux plots show that this flux follows a somewhat curved path, and it will be assumed here that the path is the arc of a circle whose center is the intersection of the extended sides of the main and commutating poles. Also, it will be assumed that the bottom of the commutating pole winding is on the same arc as the top of the main pole tip.

The magnetomotive force along the commutating pole is

$$M=\frac{4\pi TI_e}{10}\frac{(E-x)}{E} \tag{63}$$

The permeance of the path on one side of the pole is given as

$$dP_{clm}=\frac{Ldx}{(R+x)\frac{\pi}{P}} \tag{64}$$

Figure 8 (left). Development of rotor, with core replaced by additional windings

Figure 7 (left). Development of rotor, showing concentration of end turns

Figure 9 (right). Magnetomotive force pattern across end turns at a particular value of y

$$d\phi_{clm}=\frac{4PTI_eL(E-x)dx}{10E(R+x)} \tag{65}$$

$$d\Psi_{clm}=\frac{4PTI_eL(E-x)T(E-x)dx}{10E(R+x)E}$$

$$=\frac{4PT^2LI_e(E-x)^2dx}{10E^2(R+x)} \tag{66}$$

Integrating, with a factor of 2 to include both sides of the pole

$$\Psi_{clm}=\frac{8PT^2LI_e}{10E^2}\int_0^E\frac{(E-x)^2}{R+x}dx$$

$$=\frac{8PT^2LI_e}{10}\left(\left(\frac{E+R}{E}\right)^2\ln\frac{E+R}{R}-\frac{3}{2}-\frac{R}{E}\right) \tag{67}$$

This is still on a per-pole basis. Multiplying by P/a_c, and by the other terms to get total inductances, gives

$$X_{clm}=\frac{8T^2P^2L}{10^9a_c^2}\left(\left(\frac{E+R}{E}\right)^2\ln\frac{E+R}{R}-\frac{3}{2}-\frac{R}{E}\right) \tag{68}$$

Converting to inch units

$$X_{clm}=\frac{21.3T^2P^2L}{10^9a_c^2}\left(\left(\frac{E+R}{E}\right)^2\ln\frac{E+R}{R}-\frac{3}{2}-\frac{E}{R}\right) \tag{69}$$

The radius R can be evaluated in terms of the already-defined quantities. From Figure 6

$$R=\frac{D}{2}-\frac{1}{2}\left(\frac{w_c}{\sin\frac{\pi}{P}}+\frac{B}{\tan\frac{\pi}{P}}\right)+\delta+G_{max} \tag{70}$$

Adding the main and tip components of inductance gives

$$X_{cl}=\frac{255T^2LFP}{10^8a_c^2(2p_p-p_a-B-2H-2t_c)}+\frac{21.3T^2P^2L}{10^9a_c^2}\left(\left(\frac{E+R}{E}\right)^2\ln\frac{E+R}{R}-\frac{3}{2}-\frac{R}{E}\right)\text{ henrys} \tag{71}$$

Armature End Turn Inductance

The problem of determining the inductance of the armature end turns is one that has been approached in almost as many ways as there have been analysts. Each method attempts in its own way to simplify the rather complex physical configuration so that the mathematics involved will not be prohibitive.

The method presented here is used because there exists experimental data to substantiate it, see reference 5. It consists basically of superimposing all the conductors under one pole, treating them as one conductor. The inductance of this one conductor can be found in a fairly straightforward manner. The inductance of the distributed winding is then determined by applying a distribution factor.

The developed armature, with superimposed conductors, is shown in Figure 7.

In any one V-shaped coil, there will be $Z/2P$ individual conductors, each carrying current I_a. Because of commutation, the coils may be considered stationary, while the armature core rotates. The speed of the core, with the resultant eddy currents set up in the steel, means that little flux enters it. This condition may be approximated by replacing the rotor steel with more V-shaped coils, as shown in Figure 8.

If it is assumed that the diamond configuration extends not only in the x direc-

Figure 10 (right). Section through shaft of a machine showing location of equivalent conductor replacing stator end connections

tion, but in the y direction, the magnetomotive force pattern set up by the configuration is readily expressed as a Fourier series. The error introduced by such an assumption amounts to the mutual inductance between the existent coils of Figure 8 and those assumed coils extending in the plus and minus y directions. It has been shown that this error is small.

In expressing the magnetomotive force pattern of the configuration, let the region outside the diamonds in Figure 8 be defined as being at zero electromotive force. For a particular value of y, then, the magnetomotive force is a function of x, see Figure 9.

Fourier analysis of this curve gives for the m-th harmonic of magnetomotive force

$$A_m = \frac{4A}{\pi m} \cos \frac{m\pi x}{p_p} \sin \frac{m\pi y}{p_p \tan \phi} \tag{72}$$

where $m = 1, 3, 5 \ldots$.

This assumes full pitch windings.

The step value of magnetomotive force, A, is determined by the total current in the equivalent conductors of Figure 8. Since $4\pi/10.NI$ represents the magnetomotive force along a closed loop around the conductor, and since Figure 9 represents the magnetomotive force encountered in passing from one side of the conductor to the other, the magnetomotive force along its path must be one half of the total, or $2\pi/10NI$. In this case, I is I_a and N is $Z/2P$.

Therefore

$$A = \frac{\pi Z I_a}{10P} \tag{73}$$

The flux density at any point is determined by applying Maxwell's equations in the current-less region

$$\nabla \times B = 0 \tag{74}$$

Also

$$\nabla \cdot B = 0 \tag{75}$$

which is fundamental to a magnetic field.

Boundary conditions are that at $Z = 0$

$$B_x = -\frac{\partial A_m}{\partial x} \tag{76}$$

$$B_y = -\frac{\partial A_m}{\partial y} \tag{77}$$

and that as

$$B \to 0 \text{ as } Z \to \infty \tag{78}$$

Since the Z component of flux is the only one that links the coils, it is the only one of interest. Solving the foregoing equations by conventional means gives

$$B_{zm} = \frac{4A}{p_p \sin \phi} \cos \frac{m\pi x}{p_p} \sin \frac{m\pi y}{p_p \tan \phi} \times \epsilon^{-\frac{\pi m z}{p_p \sin \phi}} \tag{79}$$

Integrating this flux density over the area enclosed by one triangular conductor gives the flux linked by that conductor.

$$\phi_m = \int_0^{\frac{p_p \tan \phi}{2}} \int_{-\frac{y}{\tan \phi}}^{\frac{y}{\tan \phi}} B_{zm} dx dy$$

$$= \frac{2Ap_p}{m\pi \cos \phi} \tag{80}$$

This links with $Z/2a_a$ conductors, so that

$$\Psi_m = \frac{AZp_p}{m\pi a_a \cos \phi}$$

$$= \frac{Z^2 p_p I_a}{10mPa_a \cos \phi} \tag{81}$$

The uncorrected inductance, then, is

$$X = \sum_{1,3,5\ldots}^{\infty} m \frac{Z^2 p_p}{10^9 m P a_a^2 \cos \phi} \tag{82}$$

for one end of the machine.

The effect of superimposing the end turns can be accounted for by multiplying through by a distribution factor, K_{dm}. This is applicable to each sinusoidal component of inductance, and must be used squared, because of the effect of distribution on not only the production of magnetomotive force but because of the effect on flux linked. The distribution factor for the m-th harmonic is

$$K_{dm} = \frac{P \sin \frac{m\pi}{P}}{s \sin \frac{m\pi}{s}} \tag{83}$$

Thus, the total corrected inductance of the machine due to end turns is

$$X_{a_{end}} = 2 \sum_{1,3,5\ldots}^{\infty} m \frac{Z^2 p_p P^2 \sin^2 \frac{m\pi}{P}}{10^9 m P a_a^2 \cos \phi s^2 \sin^2 \frac{m\pi}{s}} \tag{84}$$

This equation may be simplified by observing that only the first three, say, terms of the series are necessary, and for these, $m\pi/s$ is a very small angle. Therefore, $\sin m\pi/s$ may be replaced by $m\pi/s$ with little loss of accuracy. Also, $p_p = \pi D/P$. Thus

$$X_{a_{end}} = \frac{2Z^2 D}{10^9 \pi a_a^2 \cos \phi} \sum_{1,3,5\ldots} m \frac{\sin^2 \frac{m\pi}{P}}{m^3} \tag{85}$$

Converting to inch units, assuming $\phi = 30°$

$$X_{a_{end}} = \frac{1.87 Z^2 D}{10^9 a_a^2} \sum_{1,3,5\ldots} m \frac{\sin^2 \frac{m\pi}{P}}{m^3} \text{ henrys} \tag{86}$$

Stator End Connection Inductance

The inductance of the stator end connections is likewise elusive in analysis. The connection strips between pole face bars can be lumped into one equivalent conductor, and if the inductance of this equivalent conductor can be determined, a fair estimate of the inductance of the actual connection can be made.

First, assume that the diameter of the equivalent conductor is equal to the width of the connection strips, w_s. The number of strips between two poles on one side of the machine will be $n_b/2P$. Yet they are not all of the same length, meaning that in effect, the equivalent conductor's current varies peripherally from point to point. This variation is near enough sinusoidal that the condition may be approximated by using the effective value of current, or

$$I_{se} = I_b \left(\frac{n_b}{2P}\right) \frac{1}{\sqrt{2}}$$

$$= \frac{I_b n_b}{2\sqrt{2}P} \tag{87}$$

The presence of the steel on one side of the conductor confuses the issue. Its effect could be produced by replacing the steel with an imaginary equivalent conductor on the opposite side of the steel's surface from the original conductor. The imaginary conductor must have equivalent current, I_{se}, in the same direction as in the original conductor in order to properly imitate the effect of the steel. The fact that the currents are in the same direction, with no apparent return path, plus the fact that the currents in the equivalent conductors reverse direction every pole means that an analysis using images is of dubious value.

Another method that seems to give reasonable results is to simply determine the self inductance of the equivalent conductor itself, assuming that the permeance is that of free space close about the conductor, and is zero at a distance greater than from the conductor to a pole tip. See Figure 10.

The conductor is treated as being infinite in length, so that its per-unit length inductance is

$$X_{se} = \frac{2}{10^9}\left(ln \frac{2R}{w_s} + \frac{1}{4}\right) \text{ henrys per centimeter} \tag{88}$$

Using for length $\pi D/a_b$

$$X_{se} = \frac{2\pi D}{10^9 a_b}\left(ln \frac{2R}{w_s} + \frac{1}{4}\right) \text{ henrys} \tag{89}$$

This is still the inductance of the equivalent conductor, which has $I_b n_b/2\sqrt{2}P$ amperes in it. If this conductor is broken up into parallel paths, each of which having I_b amperes, there will be $n_b/2\sqrt{2}P$ such paths, and each will have the same number of linkages as the equivalent conductor. Any one path will have $n_b/2\sqrt{2}P$ times the inductance of the equivalent conductor, and putting all these paths in series, as is the actual case, will give an inductance $n_b^2/8P^2$ times that of the equivalent conductor. Thus, the inductance per machine parallel path for one end can be found, and total machine inductance is that divided by a_b.

$$X_{s_{end}} = \frac{2\pi D n_b^2}{10^9 8 a_b^2 P^2}\left(ln \frac{2R}{w_s} + \frac{1}{4}\right) \tag{90}$$

The constant R is given by

$$R = \frac{1}{2}\sqrt{(l_b - L - w_s)^2 + h_p^2} \tag{91}$$

which assumes the equivalent conductor to be midway between the pole tip and magnet frame.

Inserting this into equation 90, converting to inch units, and doubling to include both ends, gives

$$X_{s_{end}} = \frac{4D n_b^2}{10^9 a_b^2 p^2} \times \left(ln \frac{\sqrt{(l_b - L - w_s)^2 + h_p^2}}{w_s} + \frac{1}{4}\right) \text{ henrys} \tag{92}$$

Summary of Equations

The following equations, then, are recommended for the calculation of inductance of d-c machines

$$X_G=\frac{2.66L(p_a+2G)}{10^8PG}\left(\frac{Z(p_a+2G)}{a_ap_p}-\frac{n_b}{a_b}\right)^2$$

$$X_g=\frac{31.9(t_c+2.5g)LP}{10^8g}\left(\frac{T}{a_c}+\frac{n_b}{2a_bP}-\frac{Z}{2a_aP}\right)^2$$

$$X_{al}=\frac{31.9Z^2L}{10^8a_a^2w_1}\left(d_2+\frac{d_1}{3}\right)$$

$$X_{bl}=\frac{31.9n_bL}{10^8a_b^2}\left(\frac{d_4}{3w_2}+\frac{d_3}{w_3}\right)\text{ (for open slot)}$$

$$X_{bl}=\frac{31.9n_bL}{10^8a_b^2}\left(\frac{d_4}{3w_2}+\frac{d_3}{w_3}\right)+\frac{B_td_6Ln_b}{10^8Ia_b}$$

(for closed slot, saturated)

$$X_{bl}=\frac{31.9n_bL}{10^8a_b^2}\left(\frac{d_4}{3w_2}+\frac{d_3}{w_3}\right)$$

(for closed slot, unsaturated)

$$X_{cl}=\frac{255T^2LFP}{10^8a_c^2(2p_p-p_a-B-2H-2t_c)}$$

$$+\frac{21.3T^2P^2L}{10^8a_c^2}\left[\left(\frac{E+R}{E}\right)^2 ln\frac{E+R}{R}-\frac{3}{2}-\frac{R}{E}\right]$$

$$X_{aend}=\frac{1.87Z^2D}{10^8a_a^2}\sum_{1,3,5}m\frac{\sin^2\frac{m\pi}{P}}{m^2}$$

$$X_{bend}=\frac{4Dn_b^2}{10^8a_b^2P^2}\left(ln\frac{\sqrt{(l_b-L-w_t)^2+h_p^2}}{w_t}+\frac{1}{4}\right)$$

Discussion

M. A. Baker (General Electric Company, Fort Wayne, Ind.): The authors are to be congratulated for an excellent paper on the calculation of d-c machine armature circuit inductance. The formulas derived in the paper are relatively simple and convenient to use. Inductance tests and calculations were made in Fort Wayne on several machines smaller than the examples cited in the paper, and I should like to submit these data to further test and verify the formulas presented.

These tests were made by the a-c impedance method with the fields unexcited. Current values were carried beyond the rated current of the motors, but the inductance was based on the initial slope of the volt-ampere curve. The brushes were not short circuited with jumpers on the machines tested as the authors recommend; this might have reduced the test values very slightly. Both 25- and 60-cycle currents were used, but very little difference was noted in the test values of inductance. The 25-cycle values were slightly higher in all cases. Test values obtained from the 60-cycle test are given in Table I of this discussion. There is no apparent explanation for the difference in accuracy between the first and the last two sets of data. All tests were carefully supervised and the calculations were checked. In Table I the values of C_x for the last two motors are based on the lower horsepower base speed ratings. These motors were conservatively rated for very difficult service and are capable of somewhat higher rating. Based on the thermal capacity of these motors, the *CD-1546* would have a C_x of approximately 0.40, and the *CD-1651* a C_x of 0.35.

R. B. Bross (Massachusetts Institute of Technology, Cambridge, Mass.): It appears that considerable interest has been focused on the determination of d-c machine armature circuit inductance for the purpose of providing the application engineer with information that will assist him in choosing appropriate control and protection equipment to be used with large power motors and generators. Although this is important, the creation of an economical and dependable machine to provide a required electromechanical energy conversion probably is of primary importance. Now in the case of certain small machines, such as those used in servo circuits, the inductance characteristics tend to be of first order importance while the characteristics of electromechanical energy conversion may be of secondary importance. Therefore, it is the hope of this discussor that if ever any standardized procedure is adopted for determining d-c machine armature circuit inductance, some consideration will be given to the needs of the motor designer and instrumentation engineer who must work with servo circuits where inductances and resulting values of characteristic time are very important.

With reference to the formula derived by assuming conditions shown in Figure 1 of the paper, we can note that an open, rectangular slot has been used which is characteristic of large machine design practice. In the case of a small motor, it is quite likely that a semiclosed slot would be used. This merely means that a different permeance would have to be used in this case. With reference to the formula for calculating armature end turn inductance, we can note that the assumption has been made that little flux enters the armature core because of eddy currents in the core due to rotation of the armature. In any case where the armature is not rotating, the desirability of using the formula as derived probably ought to be reconsidered. In general, intelligent use of the formulas presented in the paper probably requires a good understanding of the manner in which the formulas were derived.

John Cybulski (Naval Research Laboratory, Washington, D. C.): The authors have simplified the problem considerably through the assumption of infinite permeability in the iron path, uniform air gaps, linearity and application of the theory of superposition. They have been successful in that purpose, however a question exists as to whether the grading procedure employed in the derivations introduces complexity where there is none. There is a relatively simple approach to obtain the contribution of the conductors beneath the main pole to the armature winding inductance. From Figure 1 of the discussion, representing Figure 22 on page 386 in A. S. Langsdorf's book,[1] the following may be written:

The total number of armature conductors linked by this elementary tube of flux is $Z\,2X/\pi D$. The symbols are the same as defined by the authors. The magnetomotive force acting on the tube p is

$$\frac{4\pi}{10}\frac{Z}{\pi D}2XI_a$$

for any point, distance X, from the center of the pole. The flux density is

$$B=\frac{4}{10}\frac{Z}{D}\frac{2XI_a}{2G}$$

for any point, distance X, from the center of the pole. The total flux in the elementary tube is

$$d\phi=\frac{4}{10}\frac{Z}{GD}I_aXL\,dX$$

The total flux linkages by the elementary tube per parallel path is

$$d\psi=\frac{4}{10}\frac{ZL}{GD}I_a\,dX\frac{Z}{\pi D}\frac{2X}{a_a}$$

Table I

Rating	Inductance Calc.	Inductance 60-Cycle Test	Inductance Ratio Calc/Test	C_x or l'_a (Test)
CD 1136...Four-60 Hp-850/1,750 rpm-230 volt	0.00263	0.0026	1.0	0.435
CD 1546...Four-100/125 Hp-575/1,150 rpm-230 volt	0.00196	0.00156	1.26	0.298
CD 1651...Six-150/200 Hp-500/1,000 rpm-230 volt	0.00093	0.00072	1.29	0.263

An integration is performed to obtain total flux linkages per effective pole arc.

$$\psi = \int_{-1/2(P_a+2G)}^{1/2(P_a+2G)} \frac{Z^2 L\, I_a X^2\, dX}{10\pi G\, a_a\, D^2\pi}$$

$$= \frac{Z^2}{3}\, \frac{L I_a (P_a+2G)^3}{10\pi G\, a_a D^2}$$

The total linkages calculated per parallel path beneath all the poles becomes

$$\frac{Z^2 L\, I_a\, P\, (P_a+2G)^3}{3\, 10 G a_a\, D^2\pi}$$

which corresponds to equation 26 in the paper.

A calculation was made on a 90-horsepower, 1,750-rpm, 250-volt, 298-ampere, 4-pole semienclosed motor without pole face winding using the applicable portions of the authors' equations developed in the paper. The results are given in Table II of this discussion.

The armature and interpole inductances were measured separately at 60-cycle alternating current, giving 1,000 microhenrys and 400 microhenrys respectively, which correspond to items 5 and 8 in Table II of this discussion. A d-c method which employs flux probe coils to obtain the flux distribution in the air gap was also used, giving values for the separate armature and interpole inductances of 900 microhenrys and 2,000 microhenrys, respectively. In the d-c method of calculation the armature slot and end-turn inductance, items 1 and 4 in the table, were not taken into account. The interpole leakage contribution, item 7 in the table, also was neglected.

The explanation for the discrepancy between the measured values and those obtained using the formulas are:

In the armature case the air gap beneath the main pole is not uniform as is assumed by the authors, because of the chamfer at the pole tips. The resulting flux distribution there indicates the necessity to take this factor into account.

The contribution beneath the interpole would be much more accurate if the pole width were not assumed negligible. In that case a calculation can be made for a linear variation of mmf under the pole and, further, there will be a nonuniform air-gap, all of which results in considerably less calculated inductance. A calculation based on these corrections resulted in 810 microhenrys as compared to item 3 in Table II.

In the interpole case the reason essentially is the nonuniform air gap which is an appreciable effect where the interpole shoe width is not considered negligible. The interpoles in the subject machine are not laminated and that probably accounts for the low a-c value obtained.

Figure 1. Calculation of armature flux

The d-c buildup method of measurement of inductance has never attained an accuracy better than 90 per cent consistently, and generally the errors are as much as 40 per cent because of the difficulty in obtaining an accurate slope. It has been stated by the authors that with the measurement of terminal resistance several points on the buildup curve can be checked. It is presumed that this check will indicate the variation of inductance with current. It would be of interest to learn the result of this check.

It is agreed that a transient value of armature circuit inductance is desirable. Whether the calculated values of armature circuit inductance as determined by formulation, assuming no saturation effects due to initial conditions, will yield the maximum rate of rise of short-circuit current is open to question. The initial value of armature circuit inductance may be adequate for a time shortly after a short circuit in the determination of the maximum rate of rise of current provided the saturation effects are taken into account. However, during any transient change of armature circuit and shunt field currents the coefficients of inductance and mutual inductance as used in any differential equation may not be constant for the following reasons:

1. Saturation effects in the magnetic iron circuit as the inductance is determined by $N\, d\phi/dI$.
2. Flux lag with respect to the magnetomotive force existing in the magnetic circuit because of eddy-current effects.
3. Flux distortion effects in the air-gap which give indication of being the most important.

Summary

1. Variation of the air gap and the width of the interpole should be taken into account in a calculation of inductance.
2. Saturation effects caused by initial armature and shunt field currents should be calculated.
3. The transient behavior of inductance should be further investigated.

A. M. Harrison (Westinghouse Electric Corporation, East Pittsburgh, Pa.): I would like to congratulate the authors for their interesting paper on this subject.

The methods of calculation are substantially the same as those which we have used, except in the case of the armature end winding flux and stator end connections. As pointed out by the authors, this particular portion of the inductance has been approached in many ways by various people, and the proof of the method is that the results are in close agreement with test results.

The detailed calculation of the inductance of a d-c machine is a tedious process at best, and we have used a method of prorating from representative machines that have been tested which might be of interest. Assuming that a good test of a similar machine is available, it has been found that the inductance is approximately inversely proportional to the square of the speed and directly proportional to the square of the voltage, inversely proportional to the armature length, inversely proportional to the diameter cube and inversely proportional to the pole pitch.

The tests and calculations given in Table

* These two machines are of exactly the same rating but of somewhat different proportions. The machine in column 2 is a machine which was designed approximately 20 years ago and the machine in the first column is a machine of a relatively modern type of design.

III of this discussion might serve as additional data on this problem.

The machine in the last column is a machine which is noncompensated whereas the other three machines are compensated machines.

The line showing the calculated results in accordance with the author's paper has been added since the discussion was presented. In comparing the various components, we find relatively close agreement in all components except the armature end winding inductance. It is our opinion that the values obtained using the method described by the authors for the armature end winding inductance is too high. As a matter of fact, the discrepancy between the two detail calculation figures shown for the total inductance is very largely accounted for by the variation in the values obtained for the armature end winding inductance.

H. D. Snively and Paul B. Robinson: The authors wish to express their thanks for the very interesting and informative discussions which have been submitted. In particular, the inductance data and the various suggestions for improvements contained in these discussions are indications that the primary objects of the paper as expressed in the introduction will ultimately be fulfilled.

One of our associates has kindly pointed out that a more accurate expression for R in equation 70 is desirable, particularly for machines with small diameters and low numbers of poles, and has suggested the more correct value

$$R=\frac{D}{2}+F+G_{max}-\left[\frac{B^2}{4}+\left(\frac{B}{2\tan\frac{\pi}{P}}+\frac{w_c}{2\sin\frac{\pi}{P}}\right)^2\right]^{1/2}$$

The authors agree that the slight additional calculation necessitated by this use of this expression is justified by its improved accuracy and its more universal applicability to all sizes of machines.

R. B. Bross's point is very well taken that the general viewpoint of our paper is inclined to be that of a large machine designer. However, we hope that the presentation is in sufficient detail so that modifications such as semi-closed armature slots, multiple-turn pole face bars in single slots, and so forth can be taken care of easily.

Measurement of Insulation Resistance on Energized Systems

E. L. BRANCATO
MEMBER AIEE

A. T. McCLINTON
MEMBER AIEE

INSULATION resistance measurement of electric equipment gives an indication of the condition of the electrical insulation through a measurement of the current leakage through and/or over the surface of the insulation. These leakage currents are influenced by the dielectric state of the insulation and by the presence of moisture and other contaminants, therefore a measure of the insulation resistance of electric equipment or of a system assists greatly in determining the safety and reliability of the equipment for operation.

The insulation of electric systems of vessels tends to deteriorate with time, owing to the abundance of moisture and salt that saturates the surrounding atmosphere. This tendency, if not checked, will result in establishing one or more low-resistance paths between system and ground. This condition may endanger the operation of the electric plant, personnel, and possibly the safety of ship when electrically propelled. Thus it is important that the system insulation resistance be continuously observed so that deterioration of insulation resistance can be checked to prevent the establishment of "grounds."

This resistance can be measured easily and directly by a "megger" or other suitable ohmmeters. Their use, however, entails the de-energization of the system during the period of measurements. It is evident that this procedure is not feasible generally and is impossible where continuity of service is necessary.

At present the voltmeter method is employed on energized d-c systems. This consists in measuring with a voltmeter of known internal resistance the system voltages from each line to ground, and across both lines. The three voltage readings and meter resistance are applied to a simple formula which permits calculation of system insulation resistance. This method suffers from a number of shortcomings, namely, involved procedure of multiple measurements and calculations, inaccuracies due to variation in system voltage while obtaining voltmeter readings, and insensitivity of the voltmeter when the insulation resistance is high. It is apparent that this procedure is laborious and indirect, and does not provide the accuracy that can be obtained from measurements on de-energized systems.

Basic Concepts

A consideration of the problems involved with presently employed insulation resistance measuring devices on shipboard, an analysis of operational problems, and a study of insulation characteristics suggest that the requirements for a ground detector be that it shall contain its own source of voltage for stressing the insulation, and that it provides a direct reading with simplicity of operation.

The first requirement is satisfied by an electrically-isolated rectifier-type power supply. The magnitude of its voltage should be approximately equal to the potential of the system to be measured. The importance of proper selection of this voltage has been demonstrated by Evershed[1] and is further illustrated in Figure 1. The influence of voltage, varying from 250 to 800 volts (ohmmeter open circuit voltage), upon observed insulation resistance of electric systems ranging from 0.2 to 20 megohms is depicted. It becomes evident that the application of a voltage stress lower than the system normally experiences would result in an unrealistic measure of insulation resistance whereas the use of a voltage stress higher than system voltage may result in insulation breakdown.[2]

The second requirement can be met through the use of an ohmmeter type of instrument. Such an instrument could utilize a ratio-type meter movement, as employed in a megger, or could consist of a constant potential supply and a microammeter or a milliammeter with a scale calibrated for resistance. In order to employ such a device in a 2-wire ungrounded d-c system it is necessary to be able to select some point at which the potential of the ohm meter circuit can be impressed on the electric system. This point must be selected so that no additional potential is injected into the measuring circuit.

The basic circuit for meeting the foregoing requirement is illustrated in Figure 2. In this circuit R_A and R_B represent the distributed resistance of each line to ground for the associated circuit. The potentiometer connected between points l and m provides a means whereby a point of zero potential, namely that between G and S, can be obtained. This is obtained when the slider of the potentiometer is adjusted to give the relationship

$$\frac{R_x}{R-R_x}=\frac{R_A}{R_B} \tag{1}$$

Thus a point of zero potential has been obtained for insertion of the measuring instrument. However, the presence of the potentiometer will cause an error as given by the equation

$$\text{Error}=\frac{R_x(R-R_x)}{R}\ \text{(ohms)} \tag{2}$$

where R is the total resistance of the potentiometer. It should be noted that this error is dependent only on the poten-

Paper 50-194, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3-5, 1950. Manuscript submitted July 6, 1950; made available for printing August 31, 1950.

Figure 1 (left). Effect of ohmmeter voltage on insulation

Figure 3 (above). Error produced by balancing potentiometer in basic circuit

tiometer and independent of the insulation resistance. If this error is expressed in terms of the fractional distance, x, of the slider from l it becomes

$$\text{Error} = x(1-x)R \tag{3}$$

The relationship is plotted in Figure 3. (This applies only to a linear potentiometer.) It is evident from equation 3 that the error can be diminished by reducing the resistance value of the potentiometer; however, the reduction of this resistance is limited by the practical consideration of energy dissipation in the potentiometer. For example, on a 700-volt system a 10,000-ohm potentiometer rated 50 watts must be used. Since the reduction of potentiometer resistance to a very low value is impractical, compensation for the error was resorted to. The error, being a variable quantity, was not easily compensated alone. However, putting a second potentiometer in series with the balancing potentiometer produces a total error which is constant; that is, independent of slider position. This error could then be compensated by removing the corresponding amount of resistance from the internal circuit of the measuring instrument.

The resistance at the terminals of the compensating potentiometer, if R_{comp} is allowed to have its minimum possible value, must be given by the equation

$$R_{comp} = [0.25 - x(1-x)]R \tag{4}$$

where R is the total resistance of the balancing potentiometer. A nonlinear potentiometer having this characteristic was connected electrically in series with the balancing potentiometer, with the shafts of the two potentiometers mechanically coupled. The characteristics of the compensating potentiometer and the connections are shown in Figure 4.

Description of the Ground Detector

It becomes evident that operation of a device employing the aforementioned principles requires a circuit to detect the unbalanced voltage between the slider of the balancing potentiometer and ground, and a means of driving the balancing potentiometer to the point of zero potential or null point. Two methods have been developed for performing this operation. The first utilizes a voltmeter and

Figure 5. Schematic diagram of the ground detector

manually-controlled potentiometer. This system is illustrated in Figure 5. The detector circuit is designed to allow for observation of voltages as low as 0.25 volt, yet will not be damaged by voltages as high as several hundred volts. The ohmmeter, which is a rectifier-powered device, is normally connected between the compensating potentiometer and ground. By depressing switch 3, the operator can insert the detector, adjust the potentiometer to the null point, and then release the switch for observation of the insulation resistance as measured by the ohmmeter. The developed instrument is illustrated in Figure 6.

Another version of this principle is shown in Figure 7 wherein a d-c milliammeter, with scale calibrated for resistance, performs the dual function of ohmmeter and null detector. The advantage of simplicity and fewer components resulting therein, however, is offset by the increase in insulation stress resulting from this circuit. This point is further clarified in a subsequent section of this paper. Furthermore, such a scheme would require provisions for a constant potential at the output of the rectifier for any load current within the capabilities of the milliammeter. However, because of the possibility of zero or low resistance grounds existing, means must be provided for protecting the circuit against excessive currents. This circuit has been further simplified by eliminating the error compensating potentiometer, employed in the circuit of Figure 5, and by using a smaller (5,000 ohms) balancing potentiometer. This would introduce a maximum possible error of 1,250 ohms but by proper calibration of the milliammeter it can be reduced to ±625 ohms. This potentiometer would necessitate the dissipation of approximately 100 watts for a 700-volt system as compared to 50 watts dissipation of the corresponding potentiometer in the unit of Figure 5. If it is desired to record changes in insulation resistance the balancing operation can be made automatic, servo actuated by the unbalance voltage.

Guard System

It is important that the use of this type of instrument does not influence the value of insulation resistance of the system. Thus all leakage currents which may develop in the instrument due to dirt or moisture must by-pass the measuring circuit. This is accomplished by isolating or suspending in air all instrument wiring which is at a potential above ground, thus eliminating the possibility of leakage paths to ground. In the case of a component, or wire which cannot be thus suspended, the leakage currents to ground are intercepted by a metallic plate or shield and conducted to the guard terminal of the ohmmeter. The guard system of the ohmmeter by-passes these currents around the instrument's current coil. The guard systems are illustrated in Figures 5 and 7 for the two described ground detectors.

Effect of Ground Detector Voltage on System Stress

The employment of a ground detector on an energized circuit will alter the normal line-to-ground stress of the system owing to the injected voltage of the ohmmeter. Referring to Figure 8, it will be noted that the magnitude of the insulation leakage currents to ground, normally i_l for each line, has been modified by currents i_{m1} and i_{m1} induced by the ohmmeter voltage E_M. From inspection it may be observed that the effect of the ohmmeter currents is to raise the voltage of line A to ground and decrease correspondingly the voltage of line B.

In a normal system the line stresses are

$$e_a = \frac{R_A}{R_A + R_B} E_T \tag{5}$$

$$e_b = \frac{R_B}{R_A+R_B}E_T \qquad (6)$$

When a ground detector is connected to a system and properly balanced so that

Figure 8. Leakage currents due to components of ground detector and system voltages

$$\frac{R_A}{R_B} = \frac{R_x}{R-R_x} \qquad (7)$$

the corresponding stresses of equations 5 and 6 become

$$e_a = \frac{R_A}{R_A+R_B}E_T + \frac{R_A+R_B}{R+R_A+R_B}E_M \qquad (8)$$

$$e_b = \frac{R_B}{R_A+R_B}E_T - \frac{R_A+R_B}{R+R_A+R_B}E_M \qquad (9)$$

Owing to the fact that the value of R is very small for magnitudes of R_A and R_B greater than one megohm, the above relations may be simplified as follows

$$e_a = \frac{R_A}{R_A+R_B}E_T + E_M \qquad (10)$$

$$e_b = \frac{R_B}{R_A+R_B}E_T - E_M \qquad (11)$$

where

E_T = system voltage
E_M = ohmmeter voltage of the ground detector
e_a = voltage from line A to ground
e_b = voltage from ground to line B
R_A = insulation resistance to ground of line A
R_B = insulation resistance to ground of line B
R = total resistance of balancing potentiometer (10,000 ohms in the subject instruments)
R_x = potentiometer resistance from slider to line at balance

Consideration of equations 10 and 11 reveals that as the insulation resistance of line B is reduced to zero, the voltage to ground of line A approaches in magnitude the sum of the system plus ohmmeter voltages. If the ohmmeter's driving voltage is equal to the system voltage, the insulation stress of line B will approach twice system voltage. This stress could result in breakdown of the insulation. However, this has been averted in the developed ground detector by employing a power supply with voltage regulation characteristics shown in Figure 9. Thus a decrease in voltage accompanies a decrease in resistance below 1 megohm which results in the driving voltage adapting itself to the condition of the insulation. The maximum voltage that can be experienced by a 500-volt system under any condition may be observed in Figure 10. It is to be noted that for the higher values of insulation resistance the system stress can go above 500 volts. However,

Figure 9. Voltage regulation at terminals of ground detector

Figure 10. Possible maximum insulation stress on system, due to components of ground detector and system voltages

a consideration of the values of insulation resistance and the required ratios of the resistance for each line to ground reveals that it is highly improbable for the system to experience voltages from 750 to 1,000 volts. Furthermore, when these conditions are established the insulation resistance is sufficiently high that it can withstand the stress.

The ground detector of Figure 7 requires a power supply with no voltage regulation if the calibration of the ohmmeter is to be independent of internal leakage currents through the guard circuit. However, if the power supply is designed with sufficient voltage regulation to avoid overstressing of insulation at low values of resistance, it will result in inaccuracies when measuring in the range of approximately 0.1 megohm and above. This inaccuracy is attributed to guard circuit currents affecting the voltage at the terminals of the ohmmeter.

Results and Conclusions

The instrument, Figure 6, has been developed with a measuring range of 5,000 ohms to 10 megohms and a stressing voltage of 500 volts. During operation it has been found that null circuit can be balanced within 0.25 volt. This magnitude of unbalance has no discernible influence on the observed reading, and hence the accuracy of the unit is as high as that of the ohmmeter employed.

This instrument has been successfully employed during the major part of the year, to measure insulation resistance over a wide range of system voltages, on direct as well as alternating currents. Periodic calibration has indicated that the instrument retains its accuracy and that the performance is stable and thoroughly reliable.

This instrument can be employed to accurately measure the insulation resistance of any ungrounded d-c or a-c system whether energized or nonenergized. It contains its own source of electromotive force for stressing the insulation to its rated voltage but with such regulation as to render the stress proportional to the condition of the insulation. The unit is direct reading and simple to operate.

An Amplistat Regulator Applied to a 5-Kva 400-Cycle Aircraft Inverter

R. E. MORGAN
MEMBER AIEE

J. A. WALLEY
ASSOCIATE AIEE

A 5-KVA inverter for airborne electric systems has been developed to supply large amounts of 400-cycle power at very close regulation, quick response, high efficiency, and good wave shape. Such features are obtained through the use of an amplistat-type regulator, improved self-ventilation, and newly designed magnetic circuits. Specifically, the inverter has the electrical characteristics shown in Table I.

The regulation shown in Table I is maintained for the conditions of Table II.

This inverter weighs 105 pounds and it regulates the frequency to ±2 cycles per second as noted in Table I. It is interesting to compare this with *AN-3530*, which allows a frequency variation of ±10 cycles per second and maximum weight of 90 pounds. To show what each major component weighs, the 105 pounds may be segregated thus: motor-alternator unit, 68 pounds; regulator, 20 pounds; and other controls, 17 pounds (starting relays, and so forth). This tabulation shows that it is still necessary to pay in weight for a gain in regulation.

Although the close regulation results in some increase in size, the total volume of this inverter is 150 cubic inches less than the 2,600 cubic inches allowed by *AN-3530*. The close frequency regulation permits the use of equipment that cannot operate satisfactorily without added regulating equipment. The operation of much equipment can be improved with close frequency and voltage regulation and fast response of the regulator. Some equipment can be designed lighter and smaller, the closer the regulation of the inverter. Therefore an over-all weight and space saving on the airplane should be obtainable by the use of closer regulation. Figures 1, 2A, and 2B show the inverter, major internal components of the inverter, and the regulator.

Paper 50-195, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 6, 1950; made available for printing August 21, 1950.

Mechanical Design

The general mechanical design is conventional in that the motor and alternator have two separate magnetic circuits, two bearings support the rotor, and the motor-alternator unit is surmounted by a control box. The inverter is self-cooled with the air brought in at the center and discharged by radial-blade centrifugal fans at each end.

Electrical Design

The output winding on the alternator receives its excitation from two aiding fields which are wound on a salient-pole rotor. One of these fields is supplied continuously from the 115-volt d-c input and the other is fed from the voltage regulator. A similar arrangement is used on the motor, which has cumulative-compound field windings. There are two shunt fields, one of which is supplied from the input and the other fed by the frequency regulator. Two series fields also are provided on the motor. One of these series fields is in the circuit only during starting, and its purpose is to aid in controlling the peak inrush of starting current and its rate of decay. When the unit is started, the starting current does not exceed 1,000 per cent of full load current and it returns to 300 per cent of full load current within 0.2 second after first application of input voltage. The other series field provides extra stability in frequency while the inverter is running.

The continuous fields have important functions. Because of the magnetic amplifier principle, the amplistat must be saturated to some degree before they fire, or supply any output. Therefore, the regulated fields do not receive any appreciable power from the regulator until the output voltage of the alternator increases to a selected value. When the inverter is started, the continuous field on the alternator provides immediate initial excitation, thus insuring a build-up of alternator voltage. When the unit reaches approximately 60 per cent rated speed, the voltage is sufficient to fire the regulator. In addition, the continuous fields have another function pertaining to efficiency which is discussed now.

Efficiencies

The power required by the regulated motor and alternator fields is taken from the alternator output and rectified by the regulator. This feature provides the close regulation desired at the acceptable expense of somewhat reduced regulator

efficiency of the inverter, as compared to other types which obtain the field power directly from the d-c input. However, this reduction is minimized by designing the inverter to have an average of 31 per cent of the field excitation supplied directly to the two continuous fields. The over-all efficiency of the inverter (at full load, unity power factor) without the regulator in the circuit is 71.5 per cent. The over-all efficiency with the regulator is 68 per cent and, therefore, the regulator decreases the efficiency only 3.5 per cent. The regulator itself is approximately 42-per cent efficient.

Overspeed Protection Circuit

Another feature of the design is a circuit which protects the inverter against running away under light-motor-field conditions. Some of the possible circumstances under which the circuit would operate are:

1. Failure of the regulator for any reason to provide field excitation at start.
2. Malfunctioning of any of the regulator components under extraordinary operating conditions.
3. Loss of regulated field through lead breakage or poor connection.

The need for the circuit is increased because of the added complexity of this type of regulator and because of the magnitude of the stored energy in a 30-pound rotor rotating at 8,000 rpm. However, this necessity has been lessened somewhat by designing the regulator to be fail-safe wherever possible.

Two small relays make up the circuit. The explanation of their operation is best understood by referring to Figure 3 and following the sequence of steps at starting:

1. The on-off terminal is connected to the positive side of the input by an external switch.
2. The coil on contactor B is excited through the contact of relay K.
3. Contactor B closes and supplies power to the motor armature and the continuous fields of the motor and the alternator.
4. The inverter starts with both series fields in the circuit.
5. The regulator operates and relay L closes.
6. After the armature voltage increases to a selected value, contactor D closes and shorts out series field number 2.
7. At same time, relay K is actuated and is locked in, through its own contacts and secondary coil.

The inverter is now running under normal conditions with all the contactors and relays (B, D, K, and L) closed. If for some reason the inverter loses its regulated field power, relay L drops out, which de-energizes the coil on line contactor B. The inverter stops and all the components, except relay K, return to the standstill conditions. Since relay K is locked in by its secondary coil, the starting cycle cannot be repeated until the operator opens the external switch. This particular feature prevents the inverter from cycling in the event the protection circuit is called upon to operate.

If the regulator does not operate at

Figure 2 (A). The amplistat regulator (voltage and frequency)

Figure 6. Response of voltage and field currents from applying full load

Figure 7. Response of voltage and field currents from removing full load

start, the same sequence of steps occurs except that relay L cannot close. Therefore, after relay K is actuated and locked in, contactor B again is de-energized and the inverter stops. Summarizing, relay K performs three important functions as follows:

1. Controls coil on B contactor during normal start until regulator operates.
2. De-energizes coil on contactor B in case the regulator does not operate.
3. Prevents cycling of the inverter after the circuit once operates.

Amplistat Voltage and Frequency Regulator

The voltage and frequency regulator is a completely static unit, utilizing amplistat techniques, and requiring no warmup time. This type of regulator was developed in an effort to give good regulation, speed of response, and reliability.

The regulator consists actually of two separate amplistat regulators, one for voltage and one for frequency. Each contains two stages of amplification, and uses the output of the alternator as both the signal and the power supply. The operation of both regulators is based mainly upon utilizing differences in phase shift between the signal and the power supply, and also the slight changes in wave shape of the alternator output as load and power factor are changed. These features result in very rapid response and a high degree of stability. For example, the change in wave shape causes the frequency regulator to respond the instant a change in load occurs, without waiting for a change in the speed of the machine.

Voltage Regulator

The voltage regulator circuit is shown in Figure 4. It uses a saturated transformer as the voltage-sensing element, the output of which is applied to the first stage of the amplistat. The output of the amplistat (alternator field current) is determined primarily by the phase of the saturated transformer's output, rather than its amplitude. As the alternator voltage increases above 90 volts, the output of the saturated transformer shifts in phase in the direction to give less effect as a signal to the amplistat as illustrated in Figure 5, inserts 2 and 3. Thus the amplistat output decreases as the voltage rises, as required for regulating purposes.

The bias circuit for the first stage of the amplistat detects the changes in wave

Figure 8. The circuit diagram of the frequency regulator

Frequency regulator by use of an amplistat and a wave shape compensator

Figure 9 (A). Effect on the amplistat from shifting the phase of a negative signal in reference to the power supply voltage

Figure 9 (B). Effect on the amplistat from shifting the phase of a positive signal in reference to the power supply voltage

shape with load, and thus compensates the regulator, so as to give better regulation with less amplification. Less amplification in turn means better speed of response and a higher degree of stability. Flat regulation and even negative regulation have been achieved by such means with complete stability. Figures 6 and 7 illustrate the response time of approximately one-twenty fifth of a second obtained with this regulator.

Frequency Regulator

The frequency regulator consists of a resistance-capacitance network and a 2-stage amplistat, with wave shape change compensation, as shown in Figure 8. The resistance-capacitance network gives a signal varying in amplitude as the frequency changes, and in addition it shifts the phase of the signal with respect to the amplistat's supply to an ideal part of the phase sensitive curves, Figures 9(A), 9(B) and 10. The wave-shape change compensator permits flat frequency regulation with any variation of load at a given power factor.

The resistance-capacitance network consists of two parts: a lead network and a lag network. The former, shown as the upper part of the basic circuit, Figure 10, supplies current I_C to a control winding of the first stage of the amplistat in a direction to decrease the output (that is, a negative signal). The lag network supplies I_R to the other control field as a positive signal. I_R lags in phase by about 60 degrees, whereas I_C is leading by about 120 degrees. However, since it is full-wave rectified, the 120 degrees leading is equivalent to 60 degrees lagging, so that I_C and I_R are approximately in phase with each other. During normal operation, they stay between 45 and 75 degrees lagging in relation to the power supply.

As the inverter frequency decreases slightly, I_C decreases in amplitude and its phase shifts in a leading direction to an angle resulting in less effect on the amplistat, see Figure 9(A) and upper right of Figure 10. At the same time, I_R increases in amplitude and its phase shifts, leading to an angle having more effect on the amplistat, see Figure 9(B) and lower right of Figure 10. Therefore, the amplistat experiences a push-pull effect due to the phase shifting of I_C and I_R as well as the amplitude change.

Phase Detection

Further clarification of the operation of the saturated transformer, frequency

Figure 10. The basic circuit of the frequency regulator

Frequency regulator by use of an amplistat and a wave shape compensator

sensing circuits, and the wave-shape change compensator may be had by considering the phase detection characteristics of the amplistat.

For a constant power supply and load, a pure d-c signal will control the output of an amplistat only by change in amplitude of the signal. However, with a pulsating d-c signal (as used in this regulator), both the amplitude and the phase relationship of the signal affect the amount of amplification by the amplistat.

The effectiveness of a pulsating d-c signal at various phase shifts compared with a pure d-c signal is shown in Figures 9(A) and 9(B). These curves were obtained by applying a pulsating signal (full-wave rectified sine wave) of constant amplitude but varying phase to one of two equal control windings of an amplistat, and a pure d-c signal to the other. As the phase of the first signal was varied, the output of the amplistat was maintained constant by varying the amplitude of the pure d-c signal. The effective-current curve shows the variation of the effect on the amplistat of the pulsating d-c signal as its phase is shifted (not to be confused with an rms value).

In the case of the saturated transformer in the voltage regulator, Figure 5, insert 2 shows that while the peak voltage output increases as the supply voltage increases, the conducting time decreases, so that the average current remains relatively constant. However the phase shift of the trailing edge of the signal shifts away from the most sensitive phase angle, so that increasing alternator voltage decreases the effect of the saturated transformer signal on the first stage amplistat, thus giving a signal that drops as the supply voltage increases and vice versa.

The wave-shape change compensator utilizes the fact that in this alternator the voltage rises slightly above a sine wave in the first 90 degrees, and dips slightly in the second 90 degrees as load is applied. The actual change is a maximum of only 2 per cent in magnitude, and is somewhat exaggerated in the illustrations in Figures 4, and 5, and 8.

The amplistat is more sensitive to variations of a small negative pulse during the lagging part of each half-cycle of the power supply voltage, and to variations of a small positive pulse during the leading part of each half-cycle. Therefore, in one circuit of this regulator the signal is shifted leading to a phase position such that that dip is in the most sensitive phase and the rise in the insensitive phase. This provides a signal that effectively contains mostly the dip and relatively little of the rise. In another circuit, the signal is shifted lagging, and provides a signal that contains mostly the rise and relatively little of the dip. As a result, two signals are developed, one containing the dip and the other containing the rise. The voltage regulator uses the one containing the dip while the frequency regulator uses both.

Conclusions

A 5-kva inverter was developed to supply 400 cycles for aircraft applications where good frequency and voltage regulation are needed. The regulator has over-all regulation of $\pm 1/2$ per cent for frequency and $\pm 2 1/2$ per cent for voltage. The frequency is held better than 0.1 per cent for variation in a given power-factor load, which aids greatly in preventing one servomechanism from affecting another servomechanism through their common power supply. This regulation is obtained with a response time of one-fortieth second in frequency and one-twenty-fifth second in voltage.

This performance is obtained with better efficiency and smaller size than is required by Air Force-Navy Standard *AN-3530* for equivalent inverters with poorer regulation.

The output wave shape contains less than 5 per cent harmonics.

Discussion

H. B. James (Westinghouse Electric Corporation, Lima, Ohio): The authors have prepared an informative paper which adequately covers the work that has been accomplished to date in the development of this new application of the magnetic amplifier to the control of both voltage regulation and frequency regulation. This paper is especially timely because of the recent increased interest in the use of magnetic amplifiers for use on aircraft.

The use of the saturating transformer to produce the correct signal to the input of the first stage of the voltage regulator circuit suggests the use of a bridge circuit employing thyrite elements such that the output characteristic versus input produces an "S" shaped curve. By working on the negative slope of this characteristic the same type signal could be obtained. Have the authors considered this method of voltage sensing?

There is no mention of the effects of temperature upon the calibration of the regulator circuit. Tests have shown that the temperatures encountered in military aircraft can cause a marked change in the characteristics of a magnetic amplifier. The rectifiers used for self-saturation are particularly sensitive in this respect and also the amplifier copper windings are affected. On a particular magnetic amplifier application temperature effects were reduced by shunting the rectifier elements by a high resistance. However, the gain suffered as a result of this modification. The copper change was reduced by use of negative temperature coefficient resistors. Even with these alterations to the circuit, temperature effects were still evident.

Would the authors state how this problem was solved?

R. E. Morgan: The author of the discussion asked if a bridge of thyrite elements had been considered, and what method was used to compensate for temperature effect in the regulator.

A thyrite bridge was tried, and it worked well. However, it was found easier to compensate the saturated transformer for temperature effect. The use of the saturated transformer output, as used for the voltage sensing element, uses the saturation point of the core. Tests indicate this variation was approximately 2 per cent per 100 degrees centigrade. This is compensated by a copper resistor in its output circuit.

The temperature effect on the amplistat is small, and is absorbed in the regulation.

Tracking Radio Noise on Aircraft

T. B. OWEN
ASSOCIATE AIEE

THE SUBJECT of radio noise suppression received a great deal of attention a few years ago, when due to military considerations, large quantities of electronic equipment began to be installed in aircraft. It was found that the shielding of aircraft engine ignition systems which had been reasonably sufficient for the low- and medium-frequency equipment, was entirely insufficient for high- and very high-frequency radio equipment. In addition, quantities of electric equipment were installed: motors, actuators, dynamotors and inverters, all of which added to the problem, as frequently one motor could cause interference sufficient to completely blackout all of the communications equipment.

The problem was attacked from several angles. First, a rigorous program of bonding and shielding all of the electric equipment was initiated, extending all of the way from conduit to junction boxes. Second, line filters were applied to interference producing apparatus. The result was that in most cases it was possible to operate both the electric and radio equipment at the same time, but each airplane was an individual project in interference suppression and as a result no two radio installations were identical. In addition to this additional complexity, the weight increase was considerable, and there was no assurance that the aircraft would remain interference-free in service. Extensive modifications were made in service to correct this, generally adding filtering and shielding at the expense of more weight.

This intolerable situation has been corrected to some extent by a program of specification requirements, so that the electric equipment was made to some limits, and techniques of radio noise suppression were perfected. At this stage, instead of interference suppression being a 100 per cent cut-and-try affair, it became perhaps a 50 per cent cut-and-try.

Since then these techniques have remained relatively static, and while the specification requirements on electric apparatus are very complete and detailed, it is generally not possible to obtain equipment which will meet the specification. Further, very promising leads that had been developed along the lines of producing equipment which was inherently free of radio interference-producing capabilities were allowed to drop.

Even if it were possible to obtain specification equipment, it would still be necessary to operate on a 20 per cent cut-and-try basis, with the optimum perhaps 10 per cent, where the specifications were written on the basis of the best compromise between equipment efficiency and specification workability.

It is evident that even with the best specifications that can be hoped for, the radio engineer will have to make final checks and "fixes" to assure a radio interference-free airplane. This work may be classified as follows:

1. Engine ignition systems (loose magneto covers, loose coupling nuts, faulty shield braid, and so forth).

2. Motors, dynamotors, inverters, and actuators mounted in close proximity to radio apparatus. (Radiation fields produced by this equipment, even though in conformance with the specifications, produces intolerable interference.)

3. Same as (2) above, except mounted within radio apparatus. (Same conditions as above.)

4. Coupling within the airplane to lead-ins. (Open wire lead-ins in proximity to electric equipment or wire bundles, or shielded lead-ins running in strong fields, with radio interference currents flowing in the shield and going to ground in an antenna circuit element.)

Development of an Ignition Test Unit

In a previous publication by the author,[1] a method was briefly noted for locating faulty portions of the aircraft ignition harness. This method consisted of using a commercial VHF (very high frequency) signal generator to inject a modulated signal into the ignition harness of an engine, through a spark-plug lead, at a frequency approximating 150 megacycles, the exact frequency being unimportant. Then, by means of a noisemeter set to the generator frequency, the ignition harness was probed with a shielded loop probe to locate the points where the generator signal could be heard, usually at loose fittings, broken braid on flexible leads, and poorly fitting or loose magneto covers. It was necessary to provide the operator with a pair of headphones to facilitate testing.

Needless to say, this system was very clumsy to set up and use, besides requiring expensive laboratory apparatus out on the flight line where it could be exposed to all types of weather. This method was used with excellent results, but is not too applicable to flight line maintenance activities.

In order to make the system more generally applicable, a portable apparatus was designed and produced. Figure 1 shows the receiver and transmitter as it would be used in the field. Its portability and convenience of operation should be noted. Coupling from the transmitter to the harness at a single point through the triple-shielded lead, as shown, has been found to give sufficient signal to locate faults over the entire ignition system. This includes the magneto-to-ground leads, and so forth, in the accessory section and back of the firewall.

The transmitter is very simple, being a *6J6* dual triode operating at about 150 megacycles, and with a maximum power output of two watts. It is modulated at 1,000 cycles by a *6C4* triode. The oscil-

T. B. OWEN is with the Hughes Aircraft Company, Culver City, Calif.

Figure 1. Very high frequency signal injection and detection equipment in use on airplane engine

lator and modulator are housed in a completely shielded box, and have external provisions for adjusting the coupling to the load, and a small adjustment of the oscillator frequency. The power is transferred to the load through a constant-impedance coaxial plug, and a meter is provided to read the plate load of the oscillator.

The oscillator-modulator box, with the power supply, is contained in a small case, provided with a handle for ease in carrying. The power supply consists of a 6-volt storage battery, operating a vibrator-rectifier to supply 150 volts of direct current to the oscillator and modulator. Provisions are included for charging the battery directly from commercial frequency a-c lines.

As seen from Figure 1, the receiver is strapped directly on the operator, and while it is designed for both compactness and efficiency it is also very sensitive. There are two tubes, one a *CK556AX* hearing-aid tube operating as a super-regenerative detector, and a *30A* audio amplifier. Two standard flashlight cells provide filament power, and a small $67^1/_2$-volt "B" battery supplies plate power. Plugs for the head-phones and the loop cable are provided, and there is a knob for tuning the receiver over a small range. Since the oscillator frequency varies with loading, some such adjustment is necessary. The loop probe is electrostatically shielded, and for best results should be about 2 inches in diameter; for the location of small leaks a smaller loop is preferable, about 3/4 inch in diameter.

In use, the transmitter is coupled to the ignition harness through one of the spark plug leads, as shown in Figure 1, and the coupling adjusted for minimum output. The receiver is tuned to the transmitter frequency by loosening one of the coupling nuts on the harness, or if the engine already has a number of loose connections, it will be possible to approach the engine and tune the receiver for maximum response as sufficient signal will be present to do so. After this, probing with the loop will show the loose connections. It is only necessary to remember that the loose connection is not always where the probe shows the loudest signal, it may be at the other end of the cable. This is because the shielded loop is responsive to electromagnetic fields, and if the loose joint is voltage-fed, the current nodes that produce electromagnetic fields may be some distance away, but will always be some odd multiple of a quarter-wave at the test frequency. After the more obvious leaks are found and corrected, the power output of the oscillator to the harness is increased, and the process continued until the harness is entirely quiet. If all that is necessary is a general tightening down, an engine can be completely treated in less than a half-hour. More frequently, however, flexible cables must be replaced, or magneto covers tightened down. In any event, the testing is done on a cold engine, and there is no need for recourse to the usual cut-and-try methods of tightening down, running the engine, and so forth, or even finally replacing the entire harness because of an invisible fault in a spark-plug connection. It should be noted that the small drain holes in the distribution ring often emit a definite field that can be located by the 3/4-inch diameter loop. This field, however, has never been found to be capable of producing interference.

Consideration was given to the possibility that better results would be obtained from a square-wave generator. This would mean that the receiver would also have to be tunable over a wide range to get the best results, adding to its complexity. Experiment has shown, however, that the apparatus described gives the desired results without an extensive frequency range, and no useful purpose would be served by the added complication.

In operation, the apparatus has proved very rugged, and is readily used by flight line personnel otherwise untrained in radio-noise work.

During the initial tests of the equipment, considerable time was spent in obtaining a completely shielded oscillator compartment. For these tests, it was found that the receiver, fitted with the 3/4-inch diameter loop, was invaluable. With this loop it was possible to run along a supposedly soldered seam and find the exact spot that was unsoldered. This experience led to an extension of this method for locating radiation field leaks in other electric apparatus, chiefly motors and dynamotors.

Extension of the Signal Injection Test Method to Other Electric Apparatus

The equipment just described was so successful in locating radio interference sources in ignition systems that an extension of the test method was used to locate the radiation fields about an electric motor. Even after an excellent line filter had been applied, the radiation field about the motor in question was so heavy that a 3/4-inch diameter loop could not be brought near the motor without obtaining a full-scale meter reading when on the highest range of a commercial VHF (very high frequency) noisemeter.

A VHF signal generator and noisemeter were set up on a bench as shown in Figure 2. The output of the signal generator fed directly into the power plug on the motor control housing, the coupling lead being well shielded. A frequency of 130 megacycles was used for test.

It was found that by reducing the signal generator output, the exact location of the electromagnetic field sources could be located. In this case, the field laminations, which form a part of the body of the motor, were found to be very "hot." A copper screen was wrapped around the motor and the ends soldered together, with the screen firmly bonded to the motor case. This entirely suppressed the radiation from the field laminations.

The control box was also surrounded by various hot spots, and it was necessary to reduce the signal generator output almost to zero to locate the source. This was found to be the metal tube carrying wires from the motor to the control housing. This tube was firmly bonded to the control box at one end, and to the motor at the other. With this treatment, the radiation field about the motor and control housing completely disappeared, even at full output of the signal generator. When the motor was connected to the line

Figure 2. Laboratory setup for field determinations about an electric motor

supply for test, it was found that the radiation field around the assembly was negligible.

This method is very applicable for radiation field tests on small dynamotors and inverters which must be mounted within radio receivers. The test given in current military specifications, where a dipole antenna is mounted in close proximity to the apparatus under test, in a shielded room, is misleading and meaningless for this application. The field absorptions and reflections encountered within a shielded room are liable to give erroneous results. As has been pointed out,[2] the absolute values of the radio-influence voltages are unimportant, the test is whether or not interference is produced in radio apparatus. A piece of electric equipment that passes the radiation test of current military specifications cannot be mounted within or in close proximity to radio apparatus in most cases, as radio engineers well know. The test given here will produce a piece of apparatus that is much more adaptable to such locations.

While the tests were conducted at a frequency of 130 megacycles, the exact frequency is not important. As will be shown in the next section, the higher frequencies are preferable for these tests. The frequency chosen has the advantage that it is near the range of most aircraft VHF receivers, so that radio interference suppression at this frequency will assure that no trouble will occur in practice. For applications where the motor or inverter is to be used in radar work, the frequency used for testing could well be in the range of the equipment in which the test article is to be installed.

Characteristics of Radiation from Openings in Enclosures

As far as the present investigation is concerned, two types of enclosure are of interest: a metallic enclosure in which a strong electromagnetic field exists; and a tubular conduit or pipe containing wires which carry radio-frequency currents.

Metallic Enclosure

The type of enclosure in which we are generally interested will be a motor case, a junction box, or a magneto case.

Due to the type of radio-frequency generator contained in these enclosures, a pulse type of waveform is generated. This type of waveform can be considered as a square wave of very short duration and expansion into a Fourier series gives

$$f(t) = B_1 \sin \omega t + B_3 \sin \omega 3t + B_5 \sin \omega 5t + \ldots.$$

Thus all odd multiples of the basic exciting frequency exist within the enclosure, and fields of all these frequencies exist. Now consider the enclosure as a cavity resonator containing, of course, in the case of the motor and magneto, considerable other material. A cavity resonator of the dimensions of the ordinary motor, magneto, or junction box will have a very high resonant frequency, which will be lowered by the material composing the enclosure, and also by any magnetic material within the enclosure. Frequencies above and below this resonant frequency are attenuated. Since the Q of these enclosures is low due to the material of which they are composed, the frequency range where the fields receive relatively small attenuation is rather wide. The net result is that the lower and higher frequency fields are heavily attenuated, and the only fields of practical significance from an interference radiation standpoint are those which can exist under the conditions of a relatively low Q cavity resonator.

Large currents will flow inside the cavity, particularly at those frequencies around the resonant frequency. Wherever openings in the cavity occur at these large current regions, such as at magneto covers or junction box covers, an interruption to the current path is presented, and the current may actually flow outside the enclosure for a very small distance. At such points, a small electromagnetic field is set up, which may be detected by the loop probe, but which is undetectable by the electrostatic probe. Similarly, in motors, where the field lamination stack forms part of the motor shell, since the laminations are insulated from one another, local fields can occur outside the motor due to current flow there.

Figure 3. (A) Field configuration inside a resonant cavity. (B) External field about a break in a resonant cavity, showing coupling to proximate metallic objects

Figure 4. (A) External field about a partial break in conduit. (B) External field about a complete break in conduit

It is to be particularly noted that the fields that occur outside an enclosure which contains a source of radio-frequency energy will be almost entirely electromagnetic, and predominantly at the very-high and the ultra-high frequencies. Since the basic generator is a shock excitation device, any external fields retain this character, and so may in turn shock-excite other metallic objects within a short distance. The frequency of this secondary shock-excitation will depend upon the physical dimensions of the external excited unit, and may bear little relationship to the exciting frequency.

Referring to Figure 3, showing in outline a cavity resonator, large currents flow in the sides of the container, the electromagnetic field is circular, and the electrostatic field is vertical. This field configuration is the very simplest and is for the lowest frequency that can occur within a cylindrical cavity; other field configurations of great complexity and frequency range can also occur. An opening in the cavity in the region where the large currents are flowing permit a local current flow on the outside of the enclosure, setting up a local field, which in turn may excite a control cable, a wiring bundle, or any metallic object. The effects of this excitation may be detected often at a considerable distance from the source of the excitation, appearing as an electrostatic field at voltage nodes, and as an electromagnetic field at current nodes.

It must not be assumed from the foregoing that the only fields that occur within a cavity will be those in the region of the cavity resonant frequency. Tests run on a motor over a wide frequency range indicate that the impedance varies widely, showing that an equally valid conception would be that the motor can be considered as a generator with a multi-sectioned network as the internal imped-

ance. These investigations have not reached the point where they can be published, and it must suffice to say that in a typical motor the impedance variation is over 1,000 per cent between 15 and 150 megacycles, with a number of resonant and antiresonant points. The point of view of the motor as a cavity resonator of low Q is utilized in this paper because this explains many of the phenomena associated with the motor acting as a radio-frequency generator.

Tubular Conduit

The usual form here is a solid wall aluminum conduit, or a flexible braid conduit, in which power or control wiring may run. This wiring and the conduit enclosure may be considered as a form of coaxial cable of relatively high attenuation, since the dielectric is at least partially composed of wire insulation. It must be noted, however, that the attenuation of a coaxial cable decreases with frequency and, therefore, these conduits may form excellent transmission lines for the lower and medium frequencies. Further, these lines are practically never terminated in their characteristic impedance, so a variety of standing waves may exist, and the voltage and current relations that occur at a given point will be very complex, with voltage nodes at some frequencies and current nodes at others. The manner of excitation of these transmission lines will not be discussed except to say that we are considering radio interference generators of any of the types that exist on aircraft.

Take as a first example metallic conduit-carrying wiring which is excited over a wide frequency range. A typical case is shown in Figure 4(A), where a partial break in the conduit is shown. At the frequencies at which appreciable current is flowing on the inner surface of the conduit, a small amount of that current will flow outside the conduit at the break, in a fashion similar to a break in a cavity resonator. No electrostatic field will be detectable at the break, the loop probe must be used to detect the field. At a quarter-wave away from this point an electrostatic field will exist. Since the physical conditions that may exist in an airplane at such a joint or break may be quite varied, the structure will be very complex, and the actual location of the break will be difficult to locate. Such breaks have little significance in aircraft radio interference suppression, except, in magneto grounding circuits or other circuits of high excitation intensity, such as radar video and the trigger cables, or where an open wire lead-in runs close to the conduit. If it is necessary to locate such a break, signal injection into the circuit is about the easiest method.

The second condition that may occur is where a definite and complete break in the conduit is located, see Figure 4(B). At such a point, current nodes cannot occur, and the break will show only with the electrostatic probe. Again, current nodes will occur at a quarter-wave length from the break, and due to the geometry of aircraft structures, the field structure in the vicinity of the break will be very complex. This type of fault will not have any great significance in aircraft radio except as previously noted.

Conclusions

1. The test methods shown are particularly adaptable for the elimination of radio noise from aircraft engine ignition systems.
2. Where it is necessary to provide very close shielding for a piece of electric apparatus, the injection method is both simple and sure.
3. Present specification test methods are inadequate where the apparatus must be mounted in close proximity to, or within, a piece of radio apparatus.

The Operating Speed of D-C Brake Magnets

J. E. RYAN
MEMBER AIEE

T. M. SPITLER
NONMEMBER AIEE

D-C MAGNETS brakes are used widely in hoist and similar applications where fast and accurate positioning of the load in response to master switch manipulation is very desirable. Ideally, the brake shoes should release instantly when the master switch reaches any operating position and should set in the same way when the controller calls for braking action.

Two principal time delays prevent this ideal from being attained when picking up the shoes; these are: (1) pickup time of the controlling contactor; and (2) time for brake magnet flux to build up to the point where the shoes release. In series brakes, the first is usually the more important despite the fact that eddy currents in the solid parts of the magnet core may appreciably prevent the flux from following the rapidly rising current. For shunt brakes, the second is dominant, and since it depends upon the brake itself, the designer of that device can do something about it.

Delay in setting of the brake is caused by (1) dropout and arcing time of the controlling contactor; (2) time for eddy currents in brake magnet to decay to dropout point; and (3) mechanical travel time of shoes. The travel time of the shoes, once magnetic release has taken place, is quite short. The contactor time is usually the next larger factor, but is less important than the eddy current decay time when a proper contactor is used.

Paper 50-197, recommended by the AIEE Industrial Control Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3-5, 1950. Manuscript submitted July 5, 1950; made available for printing August 24, 1950.

J. E. Ryan is with the General Electric Company, Lynn, Mass., and T. M. Spitler is with the General Electric Company, Schenectady, N. Y.

The first part of this paper will deal with magnet pickup while the second part will consider dropout.

Pickup of Magnet

In the analysis to follow, the relations between the work required to lift the shoes, the magnet size, and the pickup time are derived. It is applicable to any type of magnet in which saturation is not appreciable in the open-gap position, but only those of one type may be compared at a time. In other words, magnets being compared must be proportional in all important dimensions in order to use the equations and curves.

Although the findings have important application in the design of brake magnets, they apply equally well to any d-c shunt magnet where the load at the initial (open-gap) position is the critical one to overcome.

Derivation

Consider a magnet with a pivoted armature such as is shown in Figure 1. In the open-gap position, the magnetomotive force required by the iron may be neglected, at least for this analysis.

The magnetic torque is

$$T = -aM^2\frac{dP}{d\theta} \tag{1}$$

With the armature at rest, and a constant voltage applied to the coil

$$M = \gamma M_o\left(1-\epsilon^{-\frac{R}{L}t}\right) \tag{2}$$

Further, the permeance P is

$$P = P_W + P_L \tag{3}$$

so that, substituting equations 2 and 3 into 1

$$T = -a\gamma^2 M_o^2\left(1-\epsilon^{-\frac{R}{L}t}\right)^2\frac{dP_W}{d\theta} \tag{4}$$

Let us now express M_o, R, L, and P_W in terms of some characteristic dimensions D. So long as proportions remain the same

$$R = \frac{kr}{D}N^2 \tag{5}$$

Then

$$Q = \frac{M_o^2 R_c}{N^2} = \frac{M_o^2 r}{D} \tag{6}$$

Q is limited by the coil surface area, so that

$$Q = hD^2 \tag{7}$$

Equating equations 6 and 7 and solving for M_o^2

$$M_o^2 = \left(\frac{h}{r}\right)D^3 \tag{8}$$

P_W can be expressed as

$$P_W = kD/\theta \tag{9}$$

so

$$\frac{dP_W}{d\theta} = \frac{-kD}{\theta^2} \tag{10}$$

As for L

$$L = N^2(P_W + P_L) = N^2\left(\frac{kD}{\theta} + lD\right) \tag{11}$$

Then, from equations 5 and 9

$$\frac{R}{L} = \frac{kr}{D^2\left(\frac{k}{\theta}+l\right)} \tag{12}$$

Substituting from the above into equation 4

$$T = \frac{ahk\gamma^2 D^4}{r\theta^2}\left[1-\epsilon^{-\left[\frac{krt}{D^2\left(\frac{k}{\theta}+l\right)}\right]}\right]^2 \tag{13}$$

Now, if γ be taken equal to α, the load torque G will be, from equation 13

$$G = \frac{ahk\alpha^2 D^4}{r\theta^2} \tag{14}$$

When, under higher excitation, $T = G$, pickup will begin. Equating equations

13 and 14 and solving

$$1-\frac{\alpha}{\gamma}=e^{-\left[\frac{\delta r t_1}{D^3\left(\frac{k}{\theta}+l\right)}\right]} \tag{15}$$

whence

$$t_1=\frac{D^3}{\delta r}\left[\frac{k}{\theta}+l\right]\ln\left[\frac{1}{1-\frac{\alpha}{\gamma}}\right] \tag{16}$$

Since W is usually a specified quantity, we can express θ better as

$$\theta=\frac{W}{G}=\frac{Wr\theta^2}{ahk\alpha^2D^4} \tag{17}$$

or

$$\theta=\frac{ahk\alpha^2D^4}{rW} \tag{17}$$

Substituting this into equation 16 and rearranging, there results

$$\frac{\delta r t_1}{lD^3}=\left[\frac{rW}{ahl\alpha^2D^4}+1\right]\ln\left[\frac{1}{1-\frac{\alpha}{\gamma}}\right] \tag{18}$$

In order to make a plot of equation 18 easier to comprehend, let

$$A=\alpha/\gamma \tag{19}$$

$$X=\frac{rW}{ahl\gamma^2D^4} \tag{20}$$

$$Y=\frac{\delta r t_1}{D^3} \tag{21}$$

Then 18 can be written

$$Y=\left[\frac{X}{A^2}+1\right]\ln\left[\frac{1}{1-A}\right] \tag{22}$$

and plotted, for various values of A, in Figure 2.

Interpretation

Note that an envelope curve uv is drawn tangent to the lowest A curve at

Figure 1. Cross section of magnetic circuit

Nomenclature

a, h, k, l, r = constants dependent only upon the proportions of the magnet type
$f(x)$ = a function of x
i = instantaneous value of current
t = time
x = length of magnetic path
D = characteristic dimension
G = load torque on armature
G_s = conductance of equivalent damping-ring
I_p = steady-state coil current when brake is energized
L = inductance of coil circuit
M = instantaneous magnetomotive force of coil
N = number of turns in coil
P = permeance of entire magnetic circuit
P_w = permeance of working flux paths
P_L = permeance of leakage flux paths
Q = power loss in coil at full rated voltage
R = resistance of coil circuit
T = magnetic torque on armature
W = work required by load
$\alpha = \dfrac{\text{voltage which picks up load in infinite time}}{\text{full rated voltage}}$
$\gamma = \dfrac{\text{voltage applied in a given instance}}{\text{full rated voltage}}$
$\delta = \dfrac{\text{total resistance of coil circuit, including external } R}{\text{coil resistance}}$
θ = armature angle
ρ = resistivity of the magnet material
φ = flux
$\propto$ = is proportional to
Subscripts pertain to:
1 = pickup
2 = dropout
a = arc
c = coil alone
o = steady-state at full rated voltage
p = primary (actual coil)
s = secondary (damping-ring)

each value of X. If W, γ, and the magnet proportions are fixed, and D is tentatively chosen, the X value is established. The minimum possible t then will correspond to the Y of the envelope curve at this X if the A value whose curve touches the envelope at this point is used.

The resultant optimum value of θ

$$\theta=\left(\frac{k}{l}\right)\frac{A}{X} \tag{23}$$

can be obtained from equations 17, 19, and 20. At large values of X, θ becomes relatively small and t increases rapidly. Indeed, if saturation had been considered, the envelope curve would rise even more rapidly toward the right-hand side, so that this always needs to be checked before using the results of Figure 2 blindly.

A study of Figure 2 also will show that, if all factors remain constant except D, and the optimum (envelope line) design is made in every case, t will steadily decrease as D increases.

If D is increased in proportion to $\sqrt[4]{W}$, the X and Y values remain fixed and

$$t_1 \propto \sqrt{W} \tag{24}$$

This appears to be a reasonable balance between size and operating time, but there is nothing uniquely advantageous about it.

An increase in leakage inductance, represented by the constant l, decreases Y less than X and thus gives a longer t, other things being equal. This is confirmed by physical reasoning.

As external series resistance is added to an otherwise fixed system, thereby making $\delta > 1.0$

$$t \propto 1/\delta \tag{25}$$

since Y is constant.

Two Magnets Versus One

Assume that a satisfactory design has been made for a single magnet capable of delivering the work required by the two shoes of a brake. Let W, D, and t_1 apply to this case.

Now design two magnets, each operating one shoe, keeping the same value of X in Figure 2. Since the work per magnet in this case, W', is

$$W'=W/2 \tag{26}$$

X will be held constant only by having

$$D'=\frac{D}{\sqrt[4]{2}} \tag{27}$$

Since Y remains the same

$$Y=\frac{\delta r t_1}{lD^3}=\frac{\delta r t_1'}{l(D')^3}$$

or

$$t_1'=\frac{t_1}{\sqrt{2}} \tag{28}$$

The total volume of the two magnets is 19 per cent greater than in the first case, but the pickup is 41 per cent faster. If the volume of the two were held strictly equal to the one larger magnet, analysis of a number of cases using Figure 2 shows that, even so, a saving of roughly 20 per cent in time is achieved.

Dropout of Magnet

Derivation

The time required for the flux to decay to the dropout point can be found by using a minor variation of a method derived by Pohl.[1] He found it possible to duplicate the effects of distributed eddy currents in the iron through the use of a

Figure 2 (above). Pick-up characteristics of d-c shunt magnets

Figure 3 (right). Various cross sections of magnetic structures

(A) Circle (B) Square (C) Rectangle (D) Rectangle with semicircular ends

fictitious short-circuited winding (damping-ring) suitably coupled with the actual coil. Although Pohl's solution is for the rise of flux in the presence of eddy currents, the decay of flux can easily be found from the same equations, once a suitable value of contactor arc resistance has been assumed.

The equivalent conductance of the fictitious damping-ring for any particular section of the magnet depends upon the cross-section and length dimensions thereof as well as the resistivity of the iron.

Referring to Figure 3, the equivalent ring conductances for several common cross sections are

Circle:

$$G_s=\frac{s}{8\pi\rho} \tag{29}$$

Square:

$$G_s=\frac{s}{32\rho} \tag{30}$$

Rectangle:

$$G_s=\frac{s}{\rho}\left[\frac{1}{12\left(\frac{w}{2d}-1\right)+32}\right] \tag{31}$$

Rectangle with semicircular ends:

$$G_s=\frac{s}{\rho}\left[\frac{1}{12\left(\frac{w}{2d}-1\right)+8\pi}\right] \tag{32}$$

To find the damping-ring conductance for the entire magnetic circuit, individual conductances for pole and yoke must be combined in the following manner:

$$G_s(\text{total})=G_s(\text{pole})+1/2G_s(\text{yoke}) \tag{33}$$

This method of combining paralle paths gives an indication as to how the damping-ring conductance for a laminated structure can be determined; namely, by finding conductances for individual laminations and combining them in a manner similar to that used in equation 33.

Pohl has also demonstrated that the substitute damping ring should have a leakage flux of 22 per cent to compensate for the fact that the actual eddy currents are distributed rather than concentrated, as in the ring.

The solution for coil current i_p, damping-ring current i_s, and flux φ, following the introduction of the arc resistance, may each be visualized as consisting of two parts: 1. the initial steady-state value; and 2. a transient quantity in the reverse direction which ultimately reaches the same magnitude as part 1. The fictitious reverse voltage V is chosen such that

$$V=I_p(R_a+R_c) \tag{34}$$

Criteria for selecting a suitable constant value of R_a will be given later.

The transformer equations of Appendix I apply, yielding as solutions

$$Ni_p=B_{1e}^{-m_1t}+B_{2e}^{-m_2t} \tag{35}$$

$$i_s=\frac{1+m_1\beta}{\omega}B_{1e}^{-m_1t}+\frac{1+m_2\beta}{\omega}B_{2e}^{-m_2t} \tag{36}$$

$$\varphi=P(Ni_p+i_s) \tag{37}$$

The quantities called for in equations 35, 36, and 37 are found from the basic variables by successive substitution as follows

$$R_s=\frac{1}{G_s} \tag{38}$$

$$n=\frac{R_a+R_c}{N^2R_s}=\frac{R_p}{N^2R_s} \tag{39}$$

$$\omega=\frac{1}{1.22n}=\frac{0.82}{n} \tag{40}$$

$$\beta=\left(\frac{P}{10^8R_s}\right)\frac{0.22}{1.22n}=\frac{0.180P}{10^8R_sn} \tag{41}$$

$$c=\left(\frac{10^8R_s}{P}\right)\frac{1+1.22n}{0.22} \tag{42}$$

$$b=\left(\frac{10^8R_s}{P}\right)^2\frac{n}{0.22} \tag{43}$$

$$m_1=\frac{-c+\sqrt{c^2-4b}}{2} \tag{44}$$

$$m_2=\frac{-c-\sqrt{c^2-4b}}{2} \tag{45}$$

$$K=\frac{1+m_1\beta}{1+m_2\beta} \tag{46}$$

$$B_1=\frac{-1}{K-1}NI_p \tag{47}$$

$$B_2=\frac{K}{K-1}NI_p \tag{48}$$

With all parameters specified, it is now possible to express φ as a function of time only. The φ corresponding to armature

Figure 4. Oscillogram showing drop-out characteristics of an 1,800-foot-pound brake with solid magnet

(A) Coil current
(B) Search coil voltage
(C) Pole face flux

release is known from the mechanical torque applied; hence, the dropout time is determined.

The analysis of Appendix I tacitly assumes constant permeance of the magnetic circuit. Yet most d-c magnets are highly saturated in the closed-gap position. Error due to this assumption can be minimized by using, for the initial ampere-turns NI_1, that value which will make the calculated initial flux φ_0 equal to the actual value

$$(NI_p)=\frac{\varphi_0}{P} \tag{49}$$

As for the assumption of constant arc resistance, this may seem quite unjustifiable. However, it has been found that the exact resistance-time characteristic of the coil circuit is relatively unimportant so long as it is such as to reduce the coil current to a small fraction of its initial value in about the same time that the actual contactor does. This is accomplished in the present analysis by using a suitable value of n, see Figure 4. Any more rigorous method would greatly complicate the mathematics.

Reference to equations 42, 43, 44, and 45 shows that m_1 normally will be considerably smaller than m_2, and therefore will be the controlling time constant. Also, the coefficient B_1 will normally be larger than B_2. Since the latter part of the flux transient is of greatest interest in determining dropout time, one may logically drop the second term of equations 35 and 36 when substituting into 37. Then

$$\varphi=PB_1\left[1+\frac{1+m_1\beta}{\omega}\right]e^{-m_1t} \tag{50}$$

which, when solved for $t=t_2$ and simplified, yields

$$t_2=-\frac{1}{m_1}ln\left[\left(\frac{\varphi_0}{\varphi_2}\right)\left(\frac{B_1}{NI_p}\right)\left(1+\frac{1+m_1\beta}{\omega}\right)\right] \tag{51}$$

Experimental Verification

Two 1,800-foot-pound brakes, one with a solid magnet and the other with a laminated one, were tested to compare the dropout times, with those calculated from equation 51 using a value of $n=10$. Results were as follows

Magnet	Dropout time, t_2, seconds Calculated	Experimental
Solid	0.29	0.24
Laminated	0.09	0.11

Figure 4 shows several oscillograph records from the solid magnet test. In Figure 4(A), the current curves for $n=5$ and $n=10$ may be compared with the experimental one. Though widely different from the latter in shape, the effect on the flux curve of Figure 4(C), is seen to be minor. Figure 4(B) shows the voltage induced in a search coil around the pole face. When integrated, this yields the experimental flux curve of Figure 4(C). The corresponding calculated curve was obtained from equation 37, the complete equation. However, at dropout, equation 51 gives practically the same value.

Variation of t_2 with Magnet Parameters

By substituting equations 32 through 48 into 51, the following proportionality can be obtained

$$t_2\propto\frac{P}{\rho}\sum\frac{z}{f\left(\frac{w}{d}\right)}ln\left[\left(\frac{\varphi_0}{\varphi_2}\right)f(n)\right] \tag{52}$$

The summation refers to the several sections of the magnet iron.

In magnets which are dimensionally similar

$$P\propto D \tag{53}$$

and

$$z\propto D \tag{54}$$

Then, when n and φ_0/φ_2 are substantially independent of magnet size, as they often are, equation 52 reduces to

$$t_2\propto\frac{D^2}{\rho} \tag{55}$$

If D is made proportional to $\sqrt[4]{W}$, as was considered reasonable in the section on Pickup of Magnet, equation 55 becomes

$$t_2\propto\frac{\sqrt{W}}{\rho} \tag{56}$$

Comparison of this with equation 24 shows that both pickup and dropout time tend to vary in the same manner with D or W.

Considering the effect of changing the load torque on a given magnet

$$\varphi_2^2\propto G \tag{57}$$

Using this in equation 52 yields

$$t_2\propto ln\frac{1}{\sqrt{G}} \tag{58}$$

The effects of changes in w/d or n can be explored if the substitutions leading to equation 52 are carried out in such a way as to preserve the actual expressions for $f(n)$ and $f(w/d)$.

Appendix I. Solution of the Transformer Equations

If a voltage V is suddenly applied to the primary of a transformer whose secondary is short-circuited, the circuit equations can be written as follows:

$$V=i_pR_p+L_p\frac{di_p}{dt}+M\frac{di_s}{dt} \tag{59}$$

$$0=i_sR_s+L_s\frac{di_s}{dt}+M\frac{di_p}{dt} \tag{60}$$

By solving these equations, current and flux can be found to be

$$i_p=B_1e^{m_1t}+B_2e^{m_2t}+I_p \tag{61}$$

$$i_s=\frac{1+m_1B}{\omega}B_1e^{m_1t}+\frac{1+m_2B}{\omega}B_2e^{m_2t} \tag{62}$$

$$\varphi=P(N_pi_p+N_si_s) \tag{63}$$

where

$$I_p=\frac{V}{R_p} \tag{64}$$

$$m_1=\frac{-c+\sqrt{c^2-4b}}{2} \tag{65}$$

$$m_2=\frac{-c-\sqrt{c^2-4b}}{2} \tag{66}$$

$$b=\frac{R_pR_s}{L_pL_s-M^2} \tag{67}$$

$$c=\frac{L_pR_s+L_sR_p}{L_pL_s-M^2} \tag{68}$$

$$K=\frac{1+m_1B}{1+m_2B} \tag{69}$$

$$B=\frac{L_pL_s-M^2}{L_sR_p} \tag{70}$$

$$\omega=\frac{MR_p}{L_sR_p} \tag{71}$$

$$B_1=\frac{1}{K-1}I_p \tag{72}$$

$$B_2=-\frac{K}{K-1}I_p \tag{73}$$

Appendix II. Evaluation of Constants a, h, k, l, and r

To evaluate the constants of the section on Pickup of Magnet that are dependent only upon the proportions of the magnet type, we can use equations 5 and 7, respectively, to find that r and h are

$$r=\frac{RD}{\delta N^2} \tag{74}$$

$$h=\frac{Q}{D^2} \tag{75}$$

By manipulating equation 11, we can obtain the following equation of a straight line

$$\frac{L}{N^2D}=l+k\frac{1}{\theta} \tag{76}$$

A plot of L/N^2D as a function of $1/\theta$ therefore results in a straight line of slope k and intercept l.

The remaining constant, a, can be evalu-

ated by solving equation 14. This gives us

$$a = \frac{Gr^2}{hka^3D^4} \tag{77}$$

All of these previously unknown constants are thus now given in terms of other constants that are either known or can be measured on a magnet of the proper proportions.

A-C Series Motors—A Design Method

SHELDON S. L. CHANG
ASSOCIATE AIEE

J. H. KARR
MEMBER AIEE

DESIGN and performance calculations for most common types of motors are well covered in the technical literature. To the uninitiated the agreement between calculated and test results, for example in polyphase motor design, may seem incredibly close. However, there is little recorded evidence of attempts to approach the design of an a-c series motor in the manner that other types of motors are designed. This situation prevails for several reasons. In the first place, almost every series motor has to be tailored to meet the requirements of the application because of the nature of its speed-torque curve. In applying an induction motor to a job, the designer is not ordinarily concerned if he is faced with using a 1/25-horsepower motor where the requirement is for 1/35-horsepower. As a matter of fact, the use of a 1/25-horsepower motor, if this is a standard rating, may be economically sound. It is usually not possible to tolerate this situation in series motor applications because of the marked difference in operating speeds at different outputs. It frequently then becomes necessary to modify motor windings to obtain the required performance on the basis of some such expedient as varying the applied voltage to the motor and proportioning windings from this data. Most series motor manufacturers have accumulated a vast background of motor performance and winding data and the experienced designer can usually select a design which approximates the requirements of the application.

Paper 50-198, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted October 19, 1949; made available for printing July 31, 1950.

Sheldon S. L. Chang and J. H. Karr are both with Robbins and Myers Incorporated, Springfield, Ohio.

In the design of any motor a knowledge of the friction and windage losses is required. This information can usually be accumulated and relied upon for constant speed motors. The problem is not so simple where series motors are involved. The motor operates over a wide speed range which means that the friction and windage losses change rapidly as the load is changed. Furthermore, a large percentage of the small series motor business involves motor parts, not complete motors. The motor designer in such instances may be required to furnish motor parts, at least in the preliminary stage of development, with very limited data on bearings, air restrictions, and other factors which affect his estimate of friction and windage losses.

All of the foregoing provides some justification for the widespread approach to the design of series motors by the method of proportion, or by the somewhat less elegant method of "cut and try."

Many situations make it desirable and necessary to design series motors by a more direct approach. It is the purpose of this paper to develop and demonstrate such a method for concentrated pole, noncompensated-type motors. The writers believe it is particularly useful in exploratory designs for new frames, to investigate possible ratings, and to contrast effects of modifying mechanical details in laminations.

An acceptable design method should take into account the following factors:

Space Distribution of Flux

At any given instant of time, the space distribution of flux deviates considerably from a sine wave. Considering the ampere turns at different points in the air gap we may visualize the flux distribution about as shown in Figure 1.

The instantaneous speed electromotive force and torque of a single conductor are proportional to the flux density. The total armature electromotive force is the sum of the electromotive forces of individual conductors and is therefore proportional to the total flux which is the integration of flux densities no matter how distributed. Likewise, the torque acting on the armature is proportional to the total flux irrespective of distribution. The nonsinusoidal flux distribution therefore has no appreciable effect on the motor performance.

Wave Forms of Voltage and Current as Functions of Time

The line voltage has a sinusoidal wave form and consists of four parts:

1. Speed voltage of the armature, V_s, which is proportional to the main flux.
2. Transformer voltage of the armature and field, V_t, which is proportional to the time derivative of the main flux.
3. Reactive voltage due to the leakage flux of the armature and field. It is proportional to the time derivative of the leakage flux.
4. Resistance voltage drop in the windings, including brush drop.

The main flux does not have the same wave shape as the current. The leakage flux and the current have about the same wave shapes since the leakage flux path is largely in air. In an ordinary series motor, voltage components (1) and (2) above are much larger than (3) and (4) and as a result the wave form of the main flux is chiefly sinusoidal while the current contains considerable third harmonic. The developed torque is principally a product of the fundamental components of flux and current. The interaction between third harmonics is small, but is always negative. If magnetic saturation is not too high, this interaction can be neglected with the knowledge that the prediction of output and efficiency will be a little optimistic.

It has been observed that in an average motor the amount of third harmonic current is less than 30 per cent. The total effective current is therefore about 1.05 times the fundamental current. In the

proposed design method, it is the effective value of the fundamental component of current to which reference is made. The actual current is then 1.05 I and the copper loss 1.1 I^2R.

Magnetization Curve

The magnetization curve used in this design method is the maximum air gap flux plotted against the effective value of net magnetizing ampere-turns. A d-c magnetization curve would not be useful because it gives the maximum flux versus maximum current. Since there is no simple relationship between peak and effective values of a nonsinusoidal current, such magnetization curves cannot be conveniently applied.

Coil Pitch, Pole Pitch, Brush Lead and Skew

When a fractional pitch winding is used, the conductors in some slots carry opposing currents. The net ampere-turns in each of these slots is zero. A winding development diagram readily shows that slots carrying currents of the same sense occupy a belt equal to the coil pitch, ψ_c, and the coil under commutation is located with its two coil sides at the two ends of this effective belt.

In choosing the angle of brush lead, there are two factors to be considered: all slots under the influence of the pole arc must be within the effective belt in order to fully utilize the gap flux; and the leading coil side of the coil under commutation should be under the influence of the pole arc in order to facilitate commutation.

These two conditions fix the angle of brush lead as

$$\theta_b = 90^\circ\ (\psi_c - \psi) \qquad (1)$$

Rotor skew is intended primarily to improve the starting performance and reduce magnetic noise. It also gives the effect of blurring the edge of the pole arc so that improved commutation results. Skewing does not reduce the torque or speed electromotive force appreciably if the slots containing opposing currents still remain outside the influence of the pole arc.

Brush Short-Circuit Loss

As pointed out by many authors, there are two voltages in time quadrature in the short-circuited coil. The speed voltage can be utilized to assist commutation by properly adjusting the brush position. The transformer voltage always introduces a loss which is inherent in the a-c series motors. There is no way to eliminate the brush loss due to transformer voltage, but an understanding of its basic nature is of some importance in designing a-c series motors. The short-circuit current due to the transformer voltage is limited in general by the brush resistance and the total inductance of the coil under commutation. At the speed and load range for which this type of motors is generally applied, the total inductance is the more important limiting factor, and the brush loss is approximately proportional to

$$\frac{W^2B^2N_a^2}{L \times RPM \times S_c}$$

for a given lamination. L is the total inductance of the short-circuited coil. Since most of the a-c series motors are highly saturated under load, L is approximately proportional to WN_a^2/B, and the brush short-circuit loss is proportional to

$$\frac{WB^3}{RPM \times S_c}$$

This relation indicates that the brush short-circuit loss depends upon the flux density and is independent of the number of armature turns as long as the total inductance L limits the current in the short-circuited turns. It is verified by experiment for higher speeds. However, this cannot be interpreted as an argument in favor of carbon brushes with low resistivity. Though the brush short-circuit current is limited by the inductance, sufficiently high resistivity is still necessary for proper brush life. The magnetic energy stored in the coil under commutation causes uneven distribution of current on the brush face, with higher current density on the trailing edge. In the extreme case such uneven current distribution causes sparking. Other conditions remaining equal, the current distribution is more uniform on a brush with higher resistivity. Thus, the high resistance brush reduces sparking and gives longer life.

Iron Loss

This is treated in another paper by the writers.[1]

Data Required for Design

A manufacturer usually has several standard laminations. He may use a given set of laminations to obtain a number of motor ratings by varying the iron stacking. The following data can be obtained by test or by calculation for each lamination:

1. A-c magnetization curve (maximum air gap flux versus net effective magnetizing ampere-turns).
2. Iron loss curve (iron loss supplied by the stator as a function of flux density and speed).
3. Mechanical load on the rotor due to iron loss and friction and windage losses as a function of flux density and speed.
4. Brush short-circuit loss.

Figure 1 (left). Air gap flux distribution

Figure 2 (below). Vector diagram of series motor

Figure 3. Series motor performance

Ratio of Stator and Rotor Ampere-Turns

The net magnetizing ampere-turns per pole at the center of the pole arc are

$$N_sI = I\left(N_f - \frac{N_aS_c\theta_b}{90\,aP}\right) \tag{2}$$

The net magnetizing ampere-turns at the leading edge of the pole are

$$N_sI - I\,\frac{N_aS_c}{aP}\,\psi$$

In order to prevent a reversal of flux, the foregoing expression must be positive. Therefore

$$N_s > \frac{N_aS_c}{aP}\,\psi \tag{3}$$

Examination of equations 1, 2, and 3 will show that

$$N_f > \frac{N_aS_c}{aP}\,\psi_c \tag{4}$$

In practice it is desirable to have N_f about equal to N_aS_c/aP. If the ratio of field ampere-turns to armature ampere turns is made too high, iron loss and stator copper loss will become excessive. A low value of this ratio results in a motor with good universal characteristics; high values improve commutation. Usual limits are 0.7 to 1.2.

Vector Diagram

The vector diagram of a series motor is shown in Figure 2.

The nature of the four components of voltage has been explained at the beginning of this paper. The gap flux, ϕ, lags the current, I, due to the stator iron loss, rotor iron loss supplied by the stator, and brush short circuit loss due to transformer voltage.

The angle β is determined from

$$\sin\beta = \frac{\text{sum of above losses}}{V_t \times I} \tag{5}$$

Equations for Torques and Voltage

$$\text{Gross torque} = 2.66 \times 10^{-6} P\phi I\,\frac{S_cN_a}{a}\cos\beta \text{ ounce feet} \tag{6}$$

$$V_s = 2.36 \times 10^{-10} P \times RPM \times \phi\,\frac{S_cN_a}{a} = V_s'\,\frac{S_cN_a}{a} \tag{7}$$

Equations 6 and 7 are derived in slightly different forms in Langsdorf's book on Theory of Alternating Current Machinery.[3]

The transformer voltage, V_t, can be written from its usual form as

$$V_t = 4.44 \times 10^{-8}\phi \times PN_t \times f = V_t'(PN_t) \tag{8}$$

In these equations the voltages and current are effective values while the flux per pole is the maximum value. Friction and windage losses and part of the rotor iron loss must be subtracted from the gross torque to obtain the net torque.

From equations 3 and 6 we obtain

$$\phi(N_sI) > \frac{\text{Gross torque} \times 10^{-8} \times \psi}{2.66P^2\cos\beta} \tag{9}$$

This equation gives a convenient starting point in designing an a-c series motor.

Design Procedure

1. Calculate the net torque, T_n, at given speeds.

2. Estimate friction and windage and mechanical load due to rotor iron loss, T_4. These are both in terms of torque. Add these to the net torque to obtain the gross torque, T_g.

3. Calculate $K = T_g \times 10^{-8}/2.66P^2\cos\beta$ In preliminary calculations use $\cos\beta = 0.98$.

4. Choose a point on the magnetization curve so that $\phi \times N_sI$ is slightly larger, say 5 per cent, than $K\psi$.

5. Having selected the operating point in (4) check friction and windage and mechanical load due to rotor iron loss for given speed and flux density. If materially different from estimates in (2), recalculate (3) and (4).

6. Calculate $V_t' = 4.44 \times 10^{-8} \times \phi \times f$.

7. Determine iron loss supplied by stator and brush short-circuit loss.

8. Calculate

$$\sin\beta = \frac{\text{stator iron loss} + \text{brush short-circuit loss}}{V_t'P(N_sI)}$$

9. Using correct values of β and gross torque, recalculate K

10. Calculate

$$\frac{IS_cN_a}{aP} = \frac{K}{\phi} \tag{10}$$

11. Calculate

$$(NI)_f = N_sI + \frac{\theta_b}{90} \times (10) \tag{11}$$

where

$$\theta_b = 90(\psi_c - \psi)$$

12. Calculate $\gamma = (11)/(10)$ and $\gamma_s = N_sI/(10)$.

13. Calculate armature reactive drop constant

$$K_3 = \left[\frac{14.4K_sK_aPW}{S_c} + \frac{1.06\lambda_p\psi^2W}{\Delta K_1 \times S.F.} + 1.8\lambda_pK_s + \frac{3.19W\lambda_p}{\Delta_x}(1-\psi)\psi^2\right]2\pi f \times 10^{-8}$$

14. Calculate field reactive drop constant

$$K_2 = 2\pi f \times 10^{-8}[7.2K_{s,f}W + 3\lambda_p]$$

15. Calculate resistive drop constant

$$K_4 = \frac{\gamma^2 l_{mf}}{CM_f} + \frac{4L_{ca}P}{S_aCM_{sa}}$$

16. Calculate speed voltage per turn

$$V_s' = 2.36 \times 10^{-10} \times P \times RPM \times \phi$$

$V_t' \gamma_t \cos \beta$

$\Sigma = V_2$

18. Determine number of armature turns

$$\frac{S_c N_a}{a} = \frac{V - V_{br}}{\sqrt{V_1^2 + V_2^2}} \qquad (18)$$

then

$$N_a = \frac{(18)a}{S_c}$$

and

$$N_f = \frac{(18)\gamma}{P}$$

19. Line current, $I = 1.05\ (10)P/(18)$.

Calculated and Test Results

Table 1 shows the design sheet for a 1/2-horsepower 10,000-rpm series motor. Performance of the motor built in accordance with this design is given in Figure 4. Comparative calculated and test results at rated torque are shown in Table II.

Table II

	Calculated	Test
Torque, ounce feet	4.2	4.2
Rpm	10,000	10,200
Horsepower output	0.500	0.510
Amperes	5.6	5.5
Watts input	562	570
Efficiency	66.3	67
Power factor	87.4	90
Armature resistance	0.913	0.875
Field resistance	0.734	0.747

Nomenclature

a = number of parallel paths in armature

B_{sc} = brush short circuit loss

CM_f = copper cross section area of field coil, circular mils

CM_{sa} = copper cross section area per armature slot, circular mils

D = diameter of armature, inches

f = line frequency, cycles per second

FE_1 = iron loss supplied by the stator

F and W = friction and windage loss

K_1 = air gap coefficient, Carter's coefficient

K_a = Adam's pitch factor correction for slot permeance

K_e = Adam's pitch factor correction for end permeance

K_s = slot constant, rotor

K_s' = slot constant, stator

l_{ca} = average length of armature conductor

l_{mf} = average length of field turn

N_a = armature turns per coil

N_f = field turns per coil

$(NI)_a$ = armature ampere-turns per pole

N_eI = effective magnetizing ampere-turns per pole

$(NI)_f$ = field ampere-turns per pole

P = number of poles

P_e' = end leakage permeance of stator

P_s' = slot leakage permeance of stator

P_e'' = end leakage permeance of rotor

P_s'' = slot leakage permeance of rotor

P_x'' = cross axis leakage permeance of rotor

P_{zz}'' = zig-zag leakage permeance of rotor

S_c = number of commutator segments

S_s = number of armature slots

$S.F.$ = saturation factor, defined as ratio of total ampere-turns to air gap ampere-turns for given gap flux

T_n = net torque, ounce feet

T_d = mechanical load on rotor due to iron loss expressed as torque, ounce feet

T_g = gross torque, ounce feet

V = line volts

V_{br} = voltage drop in brush circuit

V_s = speed voltage

V_t = transformer voltage

W = iron stacking, inches

W_i = watts input

Δ = actual air gap, inches

Δ_x = cross axis gap, inches

ψ = pole enclosure as a decimal

ψ_c = coil pitch as a decimal

B = maximum air gap flux per pole

θ_b = angle of brush lead, degrees

γ = ratio of field to armature ampere-turns per pole

γ_t = ratio of effective magnetizing ampere-turns to armature ampere-turns per pole

Discussion

L. C. Packer (Westinghouse Electric Corporation, Springfield, Mass.): The authors have made a real contribution to the art of designing noncompensated a-c series motors with their design method. This type of motor is relatively small in size and not of the glamorous type, and is generally looked upon by other motor designers as of no importance in the motor field. However, they are one of the most difficult to design. They are made by the millions every year for some of our most important household and office appliances and portable electrical tools. They are usually designed for high speeds to reduce the size and weight of the product.

The bearing and brush friction and windage will be as much as 15 per cent of the output at high speeds even with ball bearings.

The armature iron loss is relatively high due to the high-frequency and high-flux densities in the armature especially in those teeth on one side of the armature where the cross field adds to the main field flux. The variation also is greater at the high densities because of variations in punching strains and burrs. Annealing the armature laminations will help this situation.

The full load saturation can be troublesome to calculate because of the distortion caused by the cross field and demagnetizing effect. The cross field causes extremely high armature tooth and pole tip densities on the one side. A picture of this may be seen by laying out the field forms of the flux distribution. Fairly accurate full load saturation curves may be layed out from the no-load air gap and armature teeth saturation and the demagnetizing and cross field ampere turns and employing the equal area method. Another method is to take a motor of similar winding ratio and brush shift and obtain a no-load and full-load saturation by test.

Another item that can vary the results is the angle between the current and flux. This is directly proportional to the iron loss and the losses in the coils short circuited by the brush. The speed of the commutator bars under the brush is in the order of tenths of a thousandth of a second allowing very little time for the current to rise very high, therefore this loss cannot be very accurately calculated. However, tests for iron loss and short circuit losses can be taken on similar designs of winding ratio, brush shift, current, speed and flux conditions and those values used for approximating new designs.

The authors method of design is unique in their approach to the problem. My results, when using test constants in their method, were good in some respects and not very good in others. Two different load points of the same motor were tried out as follows:

1. With actual values of flux = 84,000 (max) lines, $K = 3.46 \times 10^7$ and $\psi = 0.62$, the value of N_eI was assumed.

Calculated values, $-N_a = 11.7$, $-N_f = 77.0$, -4.36 amperes, -415 watts.

Actual values, $-N_a = 11$, $N_f = 100$, 4.36 amperes, -410 watts

2. Assuming actual values flux = 84,000 (max), $N_f/N_a = 1.3$, and $I = 4.36$.

Calculated values, $N_a = 10.95$, $N_f = 99.5$, -4.61 amperes, -479 watts.

3. Using another set of actual values, $-$flux = 92,000 (max), $K = 3.78 \times 10^7$, and solving for N_eI.

Calculated values, $N_a = 13$, $N_f = 84.5$, -4.55 amperes, -520 watts.

Actual values $N_a = 11$, $N_f = 100$, -5.18 amperes, -510 watts.

4. Assuming actual values, flux, = 92,000, $N_f = 100$, $N_a = 11$, 5.18 amperes.

Calculated $N_a = 11.5$, $N_f = 105$, -5.18 amperes, 536 watts.

Actual $N_a = 11$, $N_f = 100$, 5.18 amperes, -510 watts.

The motor from which the data was used was very accurately tested, checked, and the vector diagram practically closed. Using actual values in the authors' method checked very close to actual values except the watts in calculation (2).

Calculated values of leakage flux were used which were higher than actual values which would affect the results. The short circuit losses were calculated and they could also vary the results.

The authors' method appears to give good results, except when the value N_aI is obtained from the equation $\phi N_aI = K\psi \times 1.05$. It appears to me that it would be better to solve for S_cN_aI/a in the torque equation. When actual values are substituted in this method the results are very good, but they are not so good when starting with N_aI. At least that is my experience. Maybe some point has been missed and the authors may be able to enlighten me. More use of the method also may help to get the same results obtained with methods more familiar to me.

In the equation for the speed voltage V_s the authors use a constant 2.36. Should not this constant be $2\sqrt{2}$?

The authors consider only the transformer loss in the short circuited coils. Why do they not consider the total loss which includes the rotational loss in quadrature with the transformer loss?

A. F. Puchstein (The Jeffrey Manufacturing Company, Columbus, Ohio): This paper represents a welcome attempt to provide a method of calculation suitable for student and designer. The work is set up on the basis of sinusoidal assumptions. It would have helped to give some evidence to establish the errors resulting from this. See the vector diagram in Figure 2 of the paper. Since a saturation curve is employed, observe that with the brushes on the commutator such curves are different when taken at different speeds and frequencies. As an example, Table I of the discussion gives some figures from tests on a 3/4-horsepower 110-volt 6,500-rpm motor with distributed field winding and brushes on neutral when separately excited and driven at 3,560 rpm by a second motor.

Such saturation curves would be obtained experimentally for each frame (calculation is not very feasible). They may be taken for no-load or load conditions.

For no-load, by driving the armature with an external motor and separately exciting the field with an adjustable low-voltage supply source. Read and record speed, armature volts, field resistance, field amperes, field volts, and field watts. For load conditions, some corrections would be made for armature reaction, commutation effects, and so forth.

For load conditions, connect the motor in the normal way. Provide an adjustable supply voltage and adjustable load. Read and record speed, amperes; line, field and armature volts; line, field, and armature watts. Measure field and armature circuit resistances. If a dynamometer is available, read torque also, make an allowance for rotative loss. Obtain the leakage reactances (ordinarily this means to estimate or calculate). From these, obtain the useful flux per pole (three values; should be alike, but will not be), and its phase position and

Table I

Effective Field Amperes	Effective Armature Volts DC	25 Cycles	60 Cycles
2	21.1	18.3	17.0
4	32.8	28.0	27.0
6	38.7	33.3	32.2
8	42.6	37.0	35.9
10	45.8	39.9	38.8
12	48.1	42.1	41.0

plot as a function of current. However, with small motors, the instrument losses should be corrected for, and the variable nature of brush-contact, brush and motor friction is a problem that must be taken into account in some way, as statistically. All this serves to give a bird's-eye view of the problem. But since the attainable accuracy will be limited anyway, few will have the patience to carry its solution through. The items on the calculation sheet should be numbered in the order in which they are used. A distinction should be made between calculating what a given motor will do and designing one from the ground up. The vector diagram, Figure 2 of the paper, neglects the effects of nonsinusoidal variations in current and flux, and the effects of commutation on the strength and phase of the field flux (see reference by F. Punga) though it does give an approximate method for including the effect of the commutation short-circuit loss. It assumes that the quantities in it are linear and sinusoidal, which, of course, is not true. This means that the lines of the vector diagram will not close if measured experimentally.[2] The derivation of the expressions for leakage resistance is not given.

Sheldon S. L. Chang and **J. H. Karr:** The writers appreciate very much Mr. Packer's discussion, from which we realize that one important point in our paper was not made clear. That is probably the cause of discrepancy between calculated and actual values given in Mr. Packer's discussion. Besides the mechanical dimensions, and the specified performance, that is, torque at a given speed, two other factors influence the numbers of field and armature turns, namely: the brush shift θ_b, and the ratio γ. A satisfactory design can be made as long as these two factors are within certain ranges of values. But for different values of θ_b and γ, the numbers of field and armature turns are necessarily different to give the specified torque at the specified speed.

Most of the equations given in this paper are perfectly general. They can be used for both designing new motors and checking the performance of existing motors. In designing new motors, we have to specify θ_b and γ. θ_b is specified with equation 1, and the assumption $\phi N_aI = 1.05k\psi$ automatically determines γ with the ensuing steps in the design sheet. For reasons given in the paper, the choice of values for θ_b and γ this way generally results in good efficiency. The equation $\phi N_aI = 1.05k\psi$ also makes it possible to determine a proper operating point on the magnetization curve.

In checking the performance of existing motors both of the above equations cannot be used. With a motor designed by experience, θ_b and γ generally fall within their respective ranges of acceptable values, but they cannot be expected to equal the specific values given by these equations.

Before we adopted this design method, we made extensive checks on existing motors by a somewhat different procedure. Known quantities were V, I, N_f, N_a, θ_b. The calculated quantities to be compared with actual results are watts, speed, torque, and flux per pole. The procedure is given below:

1. Calculate N_aI from equation 2.

2. Read ϕ from magnetization curve for the calculated value of N_aI.

3. Calculate V_t from equation 8.

4. Calculate γ, γ_d from actual values of N_a and N_f.

5. Calculate K_2, K_3, K_4.

6. Calculate

$$\beta = \sin^{-1} \frac{\text{stator iron loss} + \text{brush short circuit loss}}{V_tI}$$

7. Calculate the resistive and reactive voltage drop:

$$V_x = I\rho\left(\frac{S_cN_a}{a\phi}\right)^2 (K_2 + \gamma^2 K_3)$$

$$V_R = I\rho\left(\frac{S_cN_a}{a\phi}\right)^2 K_4 + V_{b'}$$

8. Calculate the voltage out of phase with V_s:

$$V_1 = V_t + V_x \cos\beta + V_R \sin\beta$$

9. Calculate the voltage in phase with V_s:

$$V_4 = \sqrt{V^2 - V_1^2}$$

10. Calculate

$$V_s = V_4 + V_x \sin\beta - V_R \cos\beta$$

where: V_s is total voltage at right angles to flux, ϕ, and V_4 is total voltage in phase with flux ϕ.

11. Calculate rpm from V_s and ϕ by equation 7.

12. Calculate gross torque from equation 9.

13. Calculate net torque $T_n = T_g - T_d$.

14. Calculate watts input by adding output and losses.

15. Compare actual and calculated values of items 11, 13, and 14.

As the foregoing procedure uses the same basic equations and vector diagram as the design procedure, equally good results can be expected.

Mr. Packer pointed out a number of factors which may introduce some variation from the calculated results. But as all

these factors are taken into account in the design procedure, the variations of these factors from their nominal values do not seem to cause any appreciable discrepancy, insofar as our experience indicates.

The constant 2.36 is an exact constant. Its derivation is given below:

The peak value of speed voltage is

$$2p\phi\times\frac{S_c N_a}{a}\times\frac{\text{rpm}}{60}\times10^{-8}$$

The effective value is

$$\sqrt{2}p\phi\times\frac{S_c N_a}{a}\times\frac{\text{rpm}}{60}\times10^{-8}$$

grouping the constants, we have

$$\frac{\sqrt{2}}{60}\times10^{-8}=2.36\times10^{-10}$$

Generally, both the speed voltage and transformer voltage can cause loss in the short-circuited coils. The loss due to transformer voltage is nearly independent of the brush shift and must be accounted for in a correct design procedure. The quadrature component, or the loss due to speed voltage depends primarily on the brush shift. For a certain value of brush shift, the speed voltage is just enough to reverse the current in the coil during commutation, and the loss is zero. This brush position is about the same for both a-c and d-c operation of the same motor. It is assumed that the actual brush position is close enough to the ideal brush position that this loss is negligible.

The writers also appreciate Mr. Puchstein's discussion. But we do not agree with Mr. Puchstein on two points:

1. That our work is set up on the basis of sinusoidal assumptions.

2. That the calculation of the saturation curve is not very feasible.

For the first point, we do not know how Mr. Puchstein would suggest to analyze a nonsinusoidal problem, other than the following:

1. To distinguish space harmonics from time harmonics.

2. To analyze the nonsinusoidal wave form into a fundamental sine wave and some harmonic sine waves, and to study their interactions.

These are done in the paper. We correct for the effect of the third harmonics wherever correction is necessary. Mr. Puchstein states that the lines of the vector diagram will not close if measured experimentally. But that does not affect the existence of the vector diagram of the fundamental sinusoidal components which does close, nor does it prevent accurate calculation of the machine performance based on the vector diagram of the fundamental waves if the effects of the harmonics are properly studied and corrected for. A close analogy is the vector diagram of a transformer. The vector diagram does not close, but that fact does not prevent the transformer engineers from calculating its performance accurately.

For the second point, most manufacturers calculate the saturation curves of their induction motors. The a-c saturation curve of a series motor can be similarly calculated with slight modification to account for the flux distribution in the armature teeth.

Mr. Puchstein listed some measured values of a saturation curve. His data show considerable difference between a-c and d-c saturation curves while the 25-cycle and 60-cycle data agree within a few per cent.

In the paper, the writers have pointed out that the d-c saturation curve cannot be used in calculating a-c series motors. There is no theoretical basis for a difference of a few per cent between the 60-cycle and 25-cycle magnetization curves, and we doubt if Mr. Puchstein's measurements are accurate enough to establish the difference of a few per cent.

Investigation and Elimination of Unusual Vibration in the Field on a Large Single-Phase Frequency Changer

W. M. H. BALLANTYNE

R. A. BAUDRY
NONMEMBER AIEE

Synopsis: This paper describes the investigation which led to the correction of vibration trouble in the stator and rotor of a large single-phase frequency changer set. The method of correction is described. Measurements taken over a period of eight years show that the cause of vibration has been permanently corrected.

THE electrification program of the Pennsylvania Railroad necessitated a large amount of single-phase 25-cycle power, most of which is supplied by large frequency changers. One of these frequency changers was installed at the Safe Harbor Water Power Corporation's power station in 1934. It consists of two synchronous machines; a 24-pole 3-phase 60-cycle motor rated at 29,000 kva at 90 per cent power and a 10-pole single-phase 25-cycle generator rated at 31,250 kva at 80 per cent power factor. The shafts of both units are solidly coupled. The speed of 300 rpm is the highest at which a 60- to 25-cycle synchronous frequency changer can be made.

Since this frequency changer must operate in parallel with other similar units on the railroad supply system, it is provided with a stator shifting device which permits control of the output. At the Safe Harbor Power Station the frequency changer can transfer power in either direction, that is, from the 60-cycle system to the 25-cycle railroad system or inversely.

The 25-cycle generator stator is supported on springs in order to reduce to a very low value the 50-cycle torque pulsations that are transmitted to the foundation.

The 25-cycle single-phase generator is a large machine having large salient poles and a very deep core subjected to great magnetic and gravity forces which sometimes result in appreciable vibrations, as was found to be the case in this machine.

Stator vibrations were masked by the normal single-phase torque pulsations and were not detected until the machine had been operated for several years and corrective measures had to be taken.

While the stator vibrations were being eliminated, indications of pole vibration were observed. The nature and cause of these vibrations could not be ascertained until vibration measurement could be made on the rotor. As a result of these vibration measurements special wedges were provided for the poles and the vibration practically eliminated.

Investigation and Correction of Stator Vibrations

Stator Construction

The stators of both 25- and 60-cycle machines are of the conventional type used for large a-c machines. The core is made of a number of punchings stacked on cold-rolled steel bars and heavily pressed together by means of rigid end plates. Each stator is built in two sections to permit shipment from the factory to the installation site. The split of the stator is located in the vertical plane, where there is more space to provide liberal flanges which hold the halves of the stator together. This also facilitates inspection and maintenance of the joint in the core. This joint is packed with fishpaper of approximately 1/32-inch thickness in order to provide a good seat at the surface of the core joint and also to prevent short-circuiting the edges of several punchings which could result in excessive eddy current losses and local high temperatures. The split of the frame is provided with a number of steel liners sufficient to provide the desired pressure at the joint of the core, as shown in Figure 1.

The split of the core is subjected to a pulsating pressure of a frequency equal to double the line frequency. In Figure 2 it is seen that when the center line of one pole is in line with the core split, no flux is passing through the surface of the split. When two poles are straddling the split, the flux is a maximum and the unit pressure acting on the surface of the split is equal to $B^2/72$ where B is the flux density in kilolines per square inch. This pulsating force is very strong in machines having a very deep core, such as the 25-cycle generator. This makes it necessary not only to provide ample pressure at the joint but also to ascertain that this pressure is continuously maintained after the machine is placed in service.

On large single-phase machines, such as this 25-cycle unit, it is the practice to support the stator on springs to reduce to a small value the pulsating load transmitted to the foundation. The spring assembly is shown in Figure 3. The springs are arranged so that they still work in compression should the stator be lifted away from the frame foot by the large torques resulting from a short circuit in the system. The flexibility of the springs is such that the natural frequency of the system formed by the stator and the springs ap-

Paper 50-199, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3-5, 1950. Manuscript submitted July 6, 1950; made available for printing August 18, 1950.

W. M. H. Ballantyne, now deceased, was with the Safe Harbor Water Power Corporation, Baltimore, Md., and J. E. Allen, now deceased, was with the Safe Harbor Water Power Corporation, Lancaster, Pa. R. A. Baudry is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

The authors wish to acknowledge the co-operation of the Safe Harbor Water Power Corporation and the Westinghouse Electric Corporation, which made it possible to find a very simple and economical solution to a vibration problem which otherwise might have become quite serious.

Figure 1. Transversal cross sections of generator and motor showing relative proportions of cores and poles

Figure 2 (below). Magnetic flux pattern in the stator core

proaches the normal speed frequency of 300 rpm. In order to eliminate the possibility of stator oscillation in the vertical direction, the stator was originally tied to the foundation by means of a vertical flexible plate, shown in Figure 4, which is rigid in the vertical direction and flexible in the tangential direction to permit the free motion of the stator under the single-phase loading or other torque pulsations.

Investigation of Vibration

When initially placed in service in 1934, the machine performed very satisfactorily. There was a small amount of 50-cycle vibration on the stator caused by the single-phase torque, but this was almost entirely absorbed by the spring mounting and not transmitted to the foundation.

In 1937, following an inspection of the machine, it was thought advisable to retighten the split of the core after minute traces of red dust had been found near the split. The machine apparently continued to operate very satisfactorily until a second inspection made in 1939. Then it was found that the parallel winding connection supports had become loose. The vibration was sufficient to have caused one bolt to cut a slot through one of the brass cleats holding the parallel connections, as shown in Figure 5. The stator coils also had become slightly loose in the slot and were retightened by adding a fiber strip under the slot wedges. The weld between the vertical tie plate and the stator was found cracked and it was rewelded.

Figure 3 (above). Stator spring mounting

Shortly after the inspection and overhaul of 1939, it was noticed that the vibration of the sheet-steel end bells enclosing the end windings had appreciably increased. At first it was believed that this increased vibration was caused by additional inspection holes which were cut in the end bells in 1939 which could have changed their natural frequency and brought about a condition of resonance. After a further increase in the amplitude of vibration and the occurrence of some cracks in the welded joints of the flange of the end bells, a thorough investigation of the vibration was made.

This investigation showed that the fundamental frequency of vibration was 50 cycles per second, the same as the frequency of the magnetic forces caused by the armature flux. The amplitude of vibration at the horizontal split of the end bells varied from 0.008 to 0.010 inch. Addition of a weight of 150 pounds at the enter of the end bells in order to try to change the natural frequency did not appreciably change the amplitude of vibration.

The amplitude of vibration continued to increase until, in 1940, it reached 0.048 inch at one of the windows. Retightening of the end bell joints and addition of rubber dampers reduced the

Figure 4 (right). Initial stator vertical supporting plate

vibrations to approximately 0.016 inch.

In the meantime the investigation was continued and showed that:

1. The vibration existed only when the field was on and was nearly proportional to the field current.

2. The amplitude of vibration did not change when the load was increased from 0 to 15,000 kw.

This last observation indicated that although the vibrations were of magnetic origin they were not caused by the leakage flux of the end windings as had been suggested.

A study of vibration measurements which had been made in 1939 indicated that the vibration of the end bells was proportional to the vertical vibration of the stator frame near the vertical plate tying the stator to the foundation. This led to the idea that the end-bell vibration might originate in the stator. The structure of the end bell is shown in Figure 6. The front wall restrains any radial movement of the flanged joint. Any radial motion of the latter near the frame will cause the complete joint to oscillate about the corner of the end bell as a fulcrum. This will cause the vibration of the end bell to be magnified by the ratio of the length of the front wall joint to the length of the axial joint between the front wall and the stator. In order to check this theory, arrangements were made to make a complete series of vibration measurements on both stator and end bell late in 1940.

The results of this investigation are shown in Figures 7, 8, and 9. The frame vibration was measured at the horizontal center line and the end-bell vibration also at the center line near the shaft where both were found to be maximum. In Figure 7 is shown the vibration of the frame and of the end bell as a function of the shaft rpm with an armature temperature of 58 degrees centigrade and a field excitation of 300 amperes. The amplitude of vibration in the stator and the end bell are proportional and reach a very large value at the normal speed of 300 rpm, thus indicating a condition of resonance at this speed. In Figure 8 are given the amplitudes of vibration of the stator at armature temperatures of 30 degrees centigrade and 47 degrees centigrade. The curves show that at 30 degrees centigrade, the resonance point is 275 rpm, and is at exactly 300 rpm at 47 degrees centigrade. As shown in Figure 9, the resonance point also changes with the field current.

These tests showed positively that the end-bell vibrations originated in the stator. The vibration of the stator is caused mainly by the dissymmetry of the splits. The large magnetic force acting on the split causes a small motion which excites the vibration. Changes in pressure at the split and between the core and stator frame cause changes in the elastic constant of the system. These pressure changes can be caused by changes in bolt or shim adjustment, armature temperature, or field strength. Under some operating conditions there was a condition of resonance which caused excessive vibration in the stator and explained the looseness of the stator coils observed and corrected in 1939. The change in the resonance condition with split bolt adjustment and with the armature temperature

Figure 7. Stator frame and end-bell resonance at beginning of investigation

also explained the freedom from vibration when the machine was placed in service. The split adjustments were first made in 1937 and about 1939 the flow of water in the air coolers was reduced to a minimum, thus increasing the temperature of the armature, bringing the stator closer to resonance, and increasing the stator and end-bell vibrations.

Figure 5 (below). Brass winding clamp. Slot cut as result of stator vibrations

Figure 6 (below). Conversion of stator radial vibration to end-bell axial vibration

Correction of Vibration

After a further analysis of the problem and tests on a small model, it was thought that the easiest way to reduce the vibration was to eliminate the resonant condition by moving the natural period of vibration of the stator away from the operating speed. It was thought that this could be accomplished by replacing the light tie plate at the bottom of the stator by a much heavier member which would change the mode of vibration of the stator.

A temporary plate was installed under the stator. This plate was first set in place with shims and jack screws. It was found necessary to remove the shims and increase the number of jack screws in order to increase the stiffness and to move the resonance point above the normal operating speed of 300 rpm. The stator vibration was thus reduced from 0.0085 to 0.0015 inch, as shown in Figure 11, which was considered satisfactory.

Figure 8 (left). Influence of winding temperature on stator frame resonance

Figure 9 (right). Influence of field current on stator frame resonance

On the basis of these tests a permanent plate, Figure 10, was made and installed. Further tests indicated that the vibration of the stator was reduced to 0.001 inch, Figure 11, and the maximum end-bell vibration near the shaft to 0.006 inch, which was considered very satisfactory.

Similar vibration measurements were made on the 60-cycle end of the set, which is of the same design but has a much smaller radial depth of core, as shown in Figure 1, where both machines are drawn to the same scale. As a result of this smaller core size the total magnetic flux across the split and, therefore, the magnetic forces are much smaller. Furthermore, the stator frame is supported on a cradle securely bolted to the foundation, thus preventing the building up of any appreciable vibrations.

Investigation and Correction of Rotor Vibrations

Study of Rotor Vibrations

The first indication of rotor vibrations was noticed during the 1939 inspection when one of the connections between the collector rings and the field coil was found to be cracked near the coil. The crack was caused by fatigue which usually results from vibration. The presence of red dust between the pole and the spider was another indication of vibration. It was thought that this vibration was resulting from a gradual loosening of the pole dovetail wedges after several years of single-phase operation. These wedges were retightened and a laminated field connector of greater flexibility was used to replace the old one made of a single thickness of copper strap.

Another indication of pole vibration also was found later in 1939 during tests made to determine the overload capacity of the frequency changer. The operating temperature of the stator windings is normally measured by temperature detectors provided with the machine, thus permitting the easy determination of the maximum permissible operating load. The damper windings of a large single-phase machine also are subjected to severe duty, and with high overload their temperature and the resulting thermal stresses increase rapidly. The measurement of temperatures and stresses of rotating parts is much more difficult than on stationary parts, and is usually much less accurate unless very elaborate equipment is used. Several attempts at measuring the temperature of the damper winding under load were made with fusible alloys. These tests indicated that the temperature of the amortisseur ring was very conservative. However, there was some doubt whether with the location of the devices first mentioned the true amortisseur winding temperature was obtained. Then it was thought that it might be possible to measure the radial expansion of the amortisseur end ring with a "de Forest scratch gauge." This gauge, described in Appendix I, can be mounted very easily on rotating parts and indicates displacements which can be measured with an accuracy of 0.0001 inch.

The mounting of this gauge on the amortisseur winding is shown in Figure 12 and is such that the radial displacement of the amortisseur end ring with respect to the upper part of the pole is recorded.

The record of the test is shown in Figure 13 and the results were entirely unexpected. The scratch gauge moving from left to right indicated that the pole first moved outward away from the amortisseur ring. On this radial displacement is superimposed a vibrating motion of 0.003 inch. Since the frequency changer was started from the 60-cycle end, there was no load on the 25-cycle machine during this starting period and the vibrating motion is apparently

Figure 10. Final stator supporting plate

Figure 11. Reduced stator vibration after installation of final stator supporting plate

caused by gravity. The frequency was not known because the scratch gauge indicates the amplitude and number of cycles, but not the frequency.

After the machine had reached full speed the scratch indications were not very clear because the vibratory motion caused the scratch gauge arm to move near the limit of its stroke and thus caused all further indications to be crowded. However, it appears that after having reached a maximum value of 0.075 inch the relative radial displacement decreased to 0.045 inch. After some additional vibrations it dropped to zero when the frequency changer was brought to rest. Because of the crowding of the indication when the machine was under load, the radial displacement due to temperature effect was not considered to be of sufficient accuracy to determine the maximum overload which could be carried by the amortisseur winding.

Two significant facts which were not expected were obtained from this test:

1. The upper part of the field coil support attached to the pole was deflecting very appreciably due to centrifugal force.
2. There was a vibratory motion of 0.003 inch between the pole and amortisseur winding.

It was thought that this vibration was caused by the gravity action in the amortisseur winding, thus causing the winding to move with respect to the pole while the machine was rotating.

It was not felt at this time that these two observations had much significance and the machine was continued in service until 1941, when a new inspection was made at the time of the vibration investigation of the stator.

At the first inspection made in January 1941, parts of the pole upper coil support holding the amortisseur bars were found to be cracked. This coil support, as shown in Figure 14, is made of aluminum sheet 1/8-inch in thickness held by the rivets which hold the pole laminations together. The fracture was due to fatigue obviously caused by pulsating loads which could result either from amortisseur winding or pole vibration. The few broken sections were removed. The remaining ones were reinforced by means of self-tapping screws placed in the punching between each two amortisseur bars, as shown in Figure 14.

Figure 12. Mounting of de Forest scratch gauge to record radial motion of amortisseur winding

Figure 14. View of amortisseur winding and repaired upper coil support

A few months later at the next shutdown, necessitated by the study of the stator vibration, some cracks were found at the neck of the dovetails of two poles. The material around the cracks was chipped out, and it was found that these cracks were only in the first lamination in one pole and in four laminations in the other. The fractures were caused by fatigue. This indicated the presence of appreciable vibrations because the tensile stress in the neck of the pole at normal speed was very low, less than one-fifth of the yield point or endurance limit of the material.

The following summary of all previous observations and troubles on the pole then was made:

1. Cracked field lead connection.
2. Scratch gauge test indicating vibration in the pole.
3. Presence of red iron oxide dust at the bottom of the pole.
4. Broken amortisseur winding support.
5. Cracked pole dovetail.

Figure 13. Scratch gauge record of radial relative motion between amortisseur ring and stud mounted on coil support

For mounting of scratch gauge, see Figure 12

Source of Rotor Vibrations

All these observations indicated that the pole itself was vibrating. After the finding of the cracked field connector, the same conclusions already had been reached and the dovetail wedges were retightened in order to eliminate was vibration which, it was then thought, was caused by gradual loosening of the pole dovetail due to the pulsating single phase torque. When considering the fastening of a pole to the spider by means of a dovetail and tapered wedge, it usually is believed that the tension produced by driving the wedges is sufficient to keep the pole tight against the spider under all operating conditions. In this case, with the large width of the pole, it was very difficult to visualize that under these conditions the pole could vibrate relative to the spider. However, by a very simple analysis it can be seen easily that for a pole of the length used in this machine the dovetail key is not of sufficient thickness to overcome the friction forces which would be developed over its complete length if the dovetail was preloaded by a force equal to or larger than the action of the centrifugal force of the pole and coil. Therefore, at normal speed the pole pulls away from the spider and is free to rock about the dovetail neck, the wide pole seat being of no benefit.

A further consideration of the scratch gauge test made in 1939 indicated that this theory was probably correct, and that the large radial displacement of the pole with respect to the amortisseur ring was probably not entirely due to the deformation of the coil support.

It then was decided to install several scratch gauges on the rotor to determine the motion of the pole with respect to the

Figure 15. Scratch gauge triggering device

1. Relative motion between parts *x* and *y* is recorded on scratch gauge, 1, by scratch arm, 2
2. Latch, 3, prevents travel of scratch arm while machine is being started and placed under desired operating conditions
3. Rubber band, 4, secured at *A* and held in tension by string secured at *E* and passing through holes *B*, *C*, and *D*. Latch is secured to rubber band by loop, 5
4. Scratch arm is put in normal operation by cutting string at *F*, allowing rubber band to contract and life latch away from scartch arm. String is cut by knife, 6, mounted on stator and moved into path of string

spider. Some consideration was first given to the use of more elaborate devices which could show the motion of the pole over a long period of operation. However, because of its simplicity the use of the scratch gauge was more desirable.

One of the limitations of the scratch gauge shown in the 1939 test was that vibration due to gravity caused the scratch gauge arm to move rapidly to the end of its stroke where all the indications became crowded and before vibrations caused by pulsating torque could be recorded. It then was concluded that the 1939 vibration recordings were caused by gravity, and that the arm had moved to the end of its stroke before the machine could be placed under load. This operation usually takes 20 minutes before all the switching operations are completed. It then was judged desirable to have a triggering device which could prevent operation of the scratch gauge until the frequency changer was placed under a desired load. Such a device was developed and installed on the pole, as shown in Figure 15. The scratch gauges were located on several poles.

A series of tests was made at normal speed under various loads. Typical scratch gauge records made during these tests are shown in Figure 16, which shows the relative motion between the base of the pole and the spider. It is seen that the base of the dovetail moves 0.021 inch away from the spider. The edges of the pole move away a slightly larger amount: 0.029 and 0.022 inch. At these latter points there are also two vibratory motions superimposed on the radial displacement, a high-frequency vibration of 0.003 inch double amplitude and a low-frequency motion of 0.002 inch having a frequency of one-fifth of the former. As previously mentioned, the scratch gauge gives the number of cycles, but having no time scale, does not indicate the frequency. However, there are two large pulsating forces acting on the poles. One force is caused by the single-phase torque of 50 cycles per second, the other resulting from the action of gravity which causes one cycle of vibration per revolution or five per second. The two superimposed vibrating motions of the pole have the same ratio of frequency as the forces just described. It seems very likely, therefore, that the two vibrating motions result from these forces.

Figure 16. Scratch gauge test: original condition before tangential wedges were driven

Test on pole number 10, May 1, 1941, 30,000-kw load, 300 rpm

The radial displacement of the pole is caused by the elastic deformation resulting from the action of centrifugal force on the dovetail and the spider. This motion is much larger at the end of the pole than at the center, due to the additional weight of the end of the field coil which is concentrated there. However, it was much larger than expected. This motion in itself is not objectionable but by freeing the base of the pole from the spider it permits the pole to oscillate freely about the neck of the dovetail.

Figure 17. Tangential tightening wedges to prevent rocking of poles

Correction of Rotor Vibrations

As a result of this test it was obvious that a more rigid fastening of the pole to the spider was necessary if the observed vibrations were to be eliminated or reduced to a very low value. This more rigid tie could be obtained on this machine by placing the dovetail under a stress greater than that caused by centrifugal action. This would keep the pole tight against the spider and prevent the observed motion. It has previously been explained in this paper that with the large axial length of this machine it was

impossible to produce such a condition with the existing wedge.

However, use of a novel method of wedging the pole as shown in Figure 17 made it possible to provide easily the desired initial stressing of the dovetail. These wedges are placed in two slots machined in the base of the pole and they can be installed from the ends of the machine. They are made of a number of segments to permit them to produce a uniform loading along the length of the pole. One stationary wedge, *E*, is locked in the upper corner of the slot and the other, the driving wedge, *D*, is pushed tangentially by a leaf spring, *C*. This leaf spring is placed under compression by a tapered key, *AB*, driven axially in the slot from the end of the machine. The force exerted by the spring is sufficient to overcome the tangential frictional force produced between the lower and upper wedges by centrifugal action even at 25-per cent overspeed.

With such an arrangement, as the speed of the machine increases and the pole moves away from the spider, the lower wedge is forced tightly between the spider and the upper wedge. The wedging angle is such that the wedges are self-locking. Thus after the machine has operated at a higher speed than normal (15-per cent overspeed) and after the speed has been reduced to normal, the wedges are compressed very tightly and restrain effectively the vibratory motion of the pole because of the resulting preloading of the dovetail.

One pole was equipped first with such a set of wedges. It was installed on the machine in order to prove the design, the method of assembling, and of removing the pole. On May 23, 1941, the machine was brought up to 15-per cent overspeed with the pole equipped with scratch gauges placed in the same locations as in the preceding test on May 1, 1941. The speed was increased in steps and the motion of the pole and wedges was measured with results as shown in Figure 18. After the pole was tightened the machine was operated under load, and scratch gauge records shown in Figure 19 indicated that the vibratory motion had been reduced to a very low value showing the effectiveness of the new wedges.

This test indicated that the radial displacement of the pole had been reduced from 0.029 and 0.022 inch to 0.012 and 0.018 inch at normal speed. Part of this displacement is due to the gauge support deflection, the other part indicates the additional displacement of the pole at its end. This latter displacement extends over a length of pole smaller than the length of the tangential wedge (6 inches), otherwise it would have been taken up by the tangential displacement of this wedge.

Scratch gauges placed between the upper coil support and the amortisseur ring showed the 5- and 50-cycle motion previously observed on the pole. This motion was caused by the other poles not yet wedged which were transmitting their motion to the amortisseur ring.

The machine was operated for one month after which time the scratch gauge tests were repeated. They showed that the wedges were still tight and that the motion had not increased. After this test it was decided to apply the tangential wedges to the other nine poles. While this work was being done it was found that several of the amortisseur bars were cracked near their ends. These cracks were caused by fatigue of the material and extended in the tangential direction. They resulted from the reaction between the poles and the amortisseur winding caused by the tangential vibration of the pole tips. It was felt that the failure might have occurred during the month of operation when the machine was operated with one pole provided with the self-tightening wedges. This restrained the tangential motion of the amortisseur ring at this pole and resulted in tangential forces acting between the amortisseur winding and the side of the slots in the other poles. Cracked bars were found in several poles around the periphery of the rotor.

Since it was not known if any of the other amortisseur bars which were apparently sound had not begun to develop fatigue cracks, it was felt that in order to avoid the possibility of a later prolonged outage of the machine it was desirable to replace all the amortisseur winding while the poles were in the manufacturer's shop for machining the slots for the tangential self-tightening wedges.

After one year of operation, an inspection of the self-tightening wedges was made and scratch gauges again installed at the leading and trailing edges of all poles. The gauges were locked in order to permit obtaining records while the machine was operated at the desired load.

Figure 20. Pole rocking tests

One set of tangential wedges and the springs were removed. They were found in good condition. These wedges were reinstalled and retightened by running the machine at 15 per cent overspeed.

Scratch gauge tests were repeated in 1943, 1945, and 1949 to determine the tightness of the assembly. The scratch gauge records of the 1945 and 1949 tests are shown in Figure 20, along with the initial readings taken in 1941. They show that in 1945 after four years of operation no appreciable vibration could be observed. However, in 1949 after seven years of operation a very small 5-cycle vibration could be detected on one pole.

When appreciable pole vibrations reappear, it will be a simple matter to run the machine at 15 per cent overspeed to bring all the wedges into the initial state of tightness and eliminate the vibration.

Scratch gauges mounted on the poles of the 60-cycle machine indicated a radial motion of the pole varying from 0.003 to 0.006 inch. At maximum load on the machine there was a very small vibration, of the order of 0.0001 inch which could hardly be detected. This is due to the fact that there is little or no single-phase torque acting on the poles of this machine; furthermore the gravity forces are much smaller, thus reducing the pulsating forces to a very small value. These measurements conformed the operating experience which shows that no maintenance from the standpoint of vibration has been required on this machine.

Conclusion

Large 300-rpm single-phase 25-cycle generators are huge machines subjected to pulsating forces acting on both the stator and the rotor.

The stator of this machine is split to permit shipment. The large magnetic forces acting on the split can cause large vibrations if the natural frequency of the stator is near the frequency of the magnetic forces. The natural frequency of the stator has been found to be a function of split adjustment, of the field current, and of the core temperature, thus making it very difficult to predict conditions of resonance. It was possible to eliminate the condition of resonance by adding a very rigid support under the stator; this, without changing the characteristics of the spring mounting used to limit the transmission of the torque pulsations to the foundation. Experience with this machine has also shown that it is possible to make a large split stator core that is entirely free of trouble with proper maintenance.

The tests which led to the elimination of the pole vibration brought a better understanding of the behavior of dovetail fastening for long large single-phase machines. Although the self-tightening wedges developed for the present machine were a very satisfactory solution, their application to a new machine is unnecessary. The same effect can be obtained by using a wider dovetail or a double dovetail, depending on the proportions of the pole. The conventional salient-pole machine usually has a pole of the same proportions as used on the 60-cycle end of the set, where the gravity and pulsating torques did not cause any vibrations which could be detected with the scratch gauge.

The development of methods of measuring stresses and vibrations in rotating machines is of invaluable help to the mechanical engineer. Without the use of such a device it would have been very difficult to determine the cause of the pole vibration and to develop a satisfactory method of eliminating it. The scratch gauge is a very accurate device which can easily be mounted on rotating parts and even without a time base can give very valuable information.

Large, slow-speed machines usually cannot be assembled in the manufacturer's plant or be operated there under normal operating conditions. Therefore, minor adjustments which are common to most new apparatus have to be solved and corrected in the field. The design of these machines is usually very sound and liberal. When vibrations occur, if the fundamental cause can be de-

termined, the cure is very often very simple, as it was in the case described in this paper.

Appendix I. The de Forest Scratch Gauge

Because of its small size and light weight, the de Forest scratch gauge is of particular value in measuring stresses in inaccessible locations in rotating parts of machines under conditions of high centrifugal or inertia forces. The gauge, however, records only the number of stress cycles and not their frequency.

With this gauge it is not necessary to have any collector rings; also, it is not subject to stray electric currents or fluxes in electric machines as are some of the more accurate electric strain gauges.

The gauge can record deformations from 0.0001 inch to 0.050 inch over a 2-inch gauge length. The record obtained is in the form of a fine scratch which indicates the exact amount of deformation. The scratch record can be measured or photographed at suitable magnification under a microscope.

The scratch gauge consists of two parts: one, the target; the other, the scratch arm which carries a special abrasive held under spring contact with the polished chrome-plated recording surface. The scratch arm is caused to progress over the target at right angles to the direction of the strain record. This is obtained by using the difference between the coefficients of static and moving friction.

Referring to Figure 12, the scratch arm is pressed upon by clip B so a considerable amount of friction is obtained. The two parts are secured in place on the test surface with the arm in the center of its travel. The arm then is moved to one side or the other by hand, which simultaneously established the zero line and sets up a restoring force in spring S. The friction under clip B is sufficient to retain the arm while there is no motion, but when strain occurs, the force of spring S causes the scratch arm to move slightly towards the center with each movement in the longitudinal direction. Some force is required to overcome the friction between the scratch arm and clip B, but this is usually negligible in comparison with the total force available.

Depending on the type of tests being run, the rate of transverse motion of the scratch arm can be varied by changing the pressure between the scratch arm and clip B and by reducing the thickness of spring S.

The record obtained is in the form of scratch marks on the target.

Discussion

J. W. Jones (Philadelphia Electric Company, Philadelphia Pa.): This paper is a valuable addition to the limited available information on operating experience with large single-phase frequency changers. Such machines present difficult design problems because of their large physical size combined with the pulsating torque and continuous heavy losses in the amortisseur windings. Much credit is due the authors for their thorough investigation of the troubles and the development of very ingenious and successful means of correction.

Troubles due to vibration have been experienced on large single-phase frequency changers of the Philadelphia Electric Company, some of which operate in parallel with the Safe Harbor machine through common supply to the Pennsylvania Railroad System. Since these troubles have some similarity to the Safe Harbor experience, it might be of interest to mention them briefly.

After several years service, fatigue fractures developed in some parts of the amortisseur windings of two 42,860-kva single-phase frequency changers. These parts were replaced with new designs to better withstand vibration but the failures continued. The thought was advanced that the trouble might be due to a combination of mechanical and thermal stresses since the machines were subject to occasional overload swings. To check this, temperature measurements were made using Tempil pellets attached to various parts of the winding. The color of the pellets changes when certain temperatures are exceeded and this showed some parts above the original design temperature limit. As a consequence new amortisseur bars were installed made of special oxygen-free silver bearing copper which has better fatigue characteristics at high temperatures.

While the performance since installing the new bars has been much improved there have been two additional broken bars and it was therefore decided to measure the vibration and strains in the amortisseur winding. For this purpose Baldwin Southwark resistance wire strain gauges were installed connected to an oscillograph through temporary slip rings. This provided time curves of the axial, radial, and tangential forces on the windings showing a very definite 5-cycle component due to the effect of gravity as observed at Safe Harbor. It was concluded that flexure of the generator shaft was the principal cause of a 5-cycle reversal of stresses which resulted in the amortisseur bar failures. These machines have multiple dovetails supporting each pole and there was no observable pole rocking. As a consequence of this test some additional improvements have been indicated and new parts have been ordered to be ready for installation if any further trouble develops.

A few vibration troubles developed on two 21,400-kva single-phase frequency changers. One involved fatigue fracture of a bolt which supports the connection between field coils. This has been corrected by replacement with alloy steel bolts of improved design. There were a few cases of severely worn brass winding clamps used for supporting the stator winding paralleling bars such as experienced at Safe Harbor. These are believed due to insufficient tightening at the time of assembly. Excessive vibration in the end bells at certain temperatures was corrected by installation of additional reinforcing ribs.

C. T. Pearce (Westinghouse Electric Corporation, Philadelphia, Pa.): This is an unusual paper in that it is devoted entirely to describing the correction of vibration on a piece of electric equipment in the field. It is obvious that the solution of this problem involved the same high degree of engineering ability as any of the subjects covered by the more usual type of AIEE technical paper. The authors are to be commended for their ability and ingenuity in the solution of this problem, and also for making this valuable information available to other AIEE members. Perhaps we should have more of this type of paper.

This paper also brings out the fact that field difficulties with large rotating machines cannot always be foreseen during design and manufacture, in addition to which complete operating tests may not be possible in the factory before shipment. The Safe Harbor Water Power Corporation deserve a great deal of credit for their co-operation with the manufacturer in carrying out this correction program on their property.

B. Van Ness, Jr. (Safe Harbor Water Power Corporation, Baltimore, Md.): This paper records the results of a 3-year battle against vibration trouble in the 25-cycle unit of a large single-phase frequency changer set. It is the record of the discovery and cure of what seemed to be a continuous series of difficulties; until we really were able to get at the root of the trouble, that is, movement from the single-phase double-frequency vibration, it appeared as though we were working on an endless task. It is also the record of a job on which hard work, persistence, ingenuity, and the courage to resort to novel designs produced a satisfactory solution to a tough problem.

As mentioned in the paper, we had indication of our troubles (Figure 13) two years before they appeared, but at that time the pressure was not sufficiently severe to force us to recognize them. When the severe field failures did appear, we tried every means within our knowledge to locate and determine the source of the difficulty. At that time vibration failures in turbine blades were being studied through a complicated series of mirrors and lights developed by Mr. Kroon and we first gave consideration to the adoption of this method. It was too costly and Mr. Baudry conceived the idea of the scratch gauge triggering device (Figure 15) which turned the scratch gauge into a usable device and thus was the key to the

discovery of our real difficulties. The scratch gauge triggering device and the novel system of tangential wedges conceived by Mr. Baudry and installed and tested by Mr. Ballantyne and Mr. Allen and their associates were so unusual and looked so much like a "Rube Goldberg" that real courage was required to put them into operation on a machine of this size and importance.

We suspect that radial pole movement is responsible for many more difficulties in salient pole machines than is generally realized. As a result of this work we believe that there has been developed a method which will be useful in many fields; certainly it has earned its salt in this case and it is still being used effectively to check the continued effectiveness of the system adopted.

While the paper rightfully points out that the application of the self-tightening wedge will not necessarily be required for a new machine, I personally feel that these wedges have been so successful in this machine that were another to be installed, I should prefer to reproduce the self-tightening wedge system rather than change the dovetail designs.

The manufacturer of this machine is to be congratulated on his willingness to make available to the industry this story of troubles, a story which should be of real value to other users.

John Parmakian (United States Bureau of Reclamation, Denver, Colo.): This paper presents an interesting account of the difficulties encountered in ascertaining the specific cause of failures due to vibration in large rotating machines. The method adopted by the authors in the solution of their problem should be found helpful by other investigators in the solution of similar vibration problems. Through analysis the engineer can often produce many probable causes for failures, but he often has to rely on measured quantities to establish the actual cause. In this particular case the authors could not use a wide choice of instruments because of the presence of stray currents within the unit. No doubt this limitation extended the time required to find the solution.

At the present time the United States Bureau of Reclamation is conducting a test program of the vibration phenomena associated with the formation of extensive fatigue cracks in the blading of large, slow speed turbines. The problem is being attacked by methods similar to those described in the paper. First, the probable causes of the cracking are determined from analysis and second, attempts are being made to isolate the actual cause from data representing measured quantities. In this particular instance the data consists of strains, accelerations, and pressures measured at locations on the turbine runner while the unit is in operation. The transmitters or pickup instruments used for these measurements have resistance-sensitive elements. Signals produced by these gauges on the rotating runner are transmitted through silver-plated collector rings and silver-graphite brushes to direct writing oscillographs. Most of the equipment for these tests was designed and built to suit the requirements for this particular problem. It is hoped that the results of these studies can be made available to the profession at a later date.

Even with good recorded data it is often very difficult to filter out the primary cause of the trouble. The ordinary methods of harmonic analysis are laborious unless special equipment designed for the purpose is available. Moreover, the solution to the vibration problem will not always result in a simple inexpensive modification as obtained by the authors. In some cases a major redesign of the faulty member or adjoining members may be required before a satisfactory solution can be found.

R. A. Baudry: The interest shown in this paper and the contributions made by the discussers are very much appreciated.

The reference made by Mr. Jones to the application of "resistance wire strain gauges" for the investigation of vibrations on two large single-phase frequency changers is noted with interest. This type of strain gauge came into wide use after the investigation at Safe Harbor was concluded. The resistance wire strain gauge is much more sensitive than the scratch gauge and also permits the measurement of the vibration frequency. With the scratch gauge the time base is lacking and the frequency of vibrations has to be assumed. However, the scratch gauge is not affected by electrostatic or magnetic fields as is the resistance wire strain gauge which on rotors of electric machines require very complete shielding. The effectiveness of this shielding is very difficult to ascertain when the strains which are being measured are caused by and have the same frequency as the above fields.

Such shielding usually requires much time and effort and in cases where the frequency of vibrations is known or can be determined by other means the scratch gauge therefore offers many advantages.

As observed by Mr. Parmakian, the use of the resistance wire strain gauge to determine the cause of vibration on a slow speed hydraulic turbine is not limited by problems of shielding. The use of collector rings permitting an accessible location of the recording equipment offers distinct advantages over the scratch gauge and permits obtaining much more complete data.

The Safe Harbor Power Company conducted similar tests on one of their turbines several years ago.

Modern gauging practice has made possible the successful investigation of many difficulties on rotating parts and has resulted in a distinct progress in the art of designing and operating large rotating equipment. As pointed out by B. Van Ness and C. T. Pearce, this type of investigation is of great value and it is hoped that the interest shown by users will lead to the publication of similar subjects.

Design Calculations for A-C Generators

DAVID GINSBERG
MEMBER AIEE

Synopsis: This paper presents simplified formulas and curves for rapid and accurate evaluation of steady-state and transient performance of a-c generators. The calculations provide for the determination of no-load, zero-power-factor and full-load field current, short-circuit ratio, leakage reactance, synchronous reactance, transient reactance, subtransient reactance, transient open-circuit and short-circuit time constants, and d-c time constant. A simple formula is proposed for rough approximation of no-load core loss. These formulas and curves apply to very small machines with semi-enclosed slots, very short air gaps and high flux densities in the iron, as well as to the larger machines covered by previous papers on this subject.

THE expanding use of electric equipment by the armed forces has created a demand for lightweight generators having exceptionally good wave form and transient performance. The greatest demand is for generators from 0.15 kw to 150 kw. It was found that many designers of a-c generators within this range of sizes completely ignored transient characteristics because of the absence of criteria for these characteristics and because they did not have the time to formulate a systematic design procedure from the various papers on the subject published over a period of more than 30 years. These papers agree with each other in principle, but differ from each other in terminology, in simplifying assumptions and in calculating methods. The difficulty of applying the results of the papers to the machines in question is that they apply predominantly to synchronous generators having open-slot stators and air gaps with a length of more than 3/4 per cent of the pole pitch. It also was found that the conventional methods of calculating the magnetomotive force required by the steel were quite inaccurate. For generators having small air gaps and highly saturated iron, the calculated and test values could differ from each other by more than 100 per cent. Such inaccuracies obscure the opportunities for design improvement which can be realized by better machine proportions, by full utilization of new materials, and by taking advantage of recent developments in automatic regulators. It is the purpose of this paper to extend and simplify the results of the published literature on the subject and to formulate a systematic design procedure which can be applied with accuracy to the machines in question.

Paper 50-201, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted September 16, 1949; made available for printing August 7, 1950.

DAVID GINSBERG is with the United States Army Engineer Research and Development Laboratories, Fort Belvoir, Va.

The author wishes to express his appreciation to Leo J. Misenheimer and R. Powers for their assistance in preparing this paper.

A-C Generator Design Sheets

This procedure follows Kilgore's[1] methods and terminology, where applicable. It is incorporated in a 2-page design sheet, Figures 1 and 2, in which an actual generator design is worked out as an example. The calculation of all but seven quantities can be completed from information directly available on the design sheets and without reference to any other curves or formulas. The seven quantities which require supplementary data for their determination are C_1, C_p, steel magnetization curves, core-loss factors, slot constant K_1, and chording leakage factor K_2. The factor Z on the bottom of Figure 2 represents the effect of the pole embrace on the tooth-tip and zig-zag leakages and the derivation was based on considerations presented in a 1918 paper by Doherty and Shirley.[2]

Fundamental of the Field Form C_1

This constant (denoted by Wieseman[3] as A_1) is the ratio of the peak fundamental flux density of the no-load field form to the peak actual flux density of the field form. Values of C_1 are given on Figure 3 in terms of the pole embrace and the ratio of maximum air gap to minimum air gap. The ratio of air gap to pole pitch has been ignored and, in this respect these curves differ from those of Wieseman.[3] The values were derived by ignoring the flux in the interpolar spaces, assuming that the flux density at any point under the pole shoe is inversely proportional to the air gap length at that point, and applying the Fourier integral to obtain the magnitude of the fundamental. Although the flux in the interpolar space is large enough to have a slight effect on some design constants, it has a negligible effect on C_1 because it is far removed from the pole axis and its main contribution is to the harmonic content of the flux wave. Although this assumption may not be justified for machines with very large ratios of air gap to pole pitch having very small values of pole embrace, it is justified by tests and calculations of all machines within the writer's experience. A comparison of calculated and test results for various machines is listed in Table I. Full test data is not available for all machines, since the tests were made by various agencies and were not, in general, intended for use in design studies. Further experimental verification has been obtained by the use of exploring coils to make oscillograms of the no-load field forms of a number of generators. These field forms were then analyzed to compare the actual values of C_1 (and C_p) with the calculated values.

The elimination of the ratio of air gap to pole pitch as a parameter makes it possible to express the values of C_1 by means of a single family of curves and to apply these curves to machines whose dimensions are outside the range of Wieseman's[3] curves. These curves, like Wieseman's, were calculated for pole faces which form a continuous arc of a

single circle whose radius is located on a radial line through the center of the pole embrace.

The simplification of the curves for C_1 make it easy to tell by inspection how changes of pole embrace and pole face shape will affect certain design constants. Work now is being done to utilize these simplified curves for C_1 and the simplified curves for C_p, discussed in the following, into an analytical method of predetermining machine dimensions from the specified performance requirements.

Pole Constant C_p

Curves for the determination of C_p are included in Figure 3, which also contains the curves for C_1 discussed previously. The curves for the portion of the flux under the pole, were derived analytically using the simplifying assumptions previously discussed in connection with the C_1 curves except, of course, that a direct integration of flux density over the pole embrace was substituted for the Fourier integral. In order to take account of the flux in the interpolar spaces a correction factor for C_p also is plotted in Figure 3. The correction factor was obtained by plotting Wieseman's[3] values of K_ϕ against the ratio of air gap to pole pitch and averaging the results for various ratios of maximum gap to minimum gap. The values of C_p, which represents the ratio of the average flux density to the actual peak flux density of the field form, can not be obtained directly from Wieseman's paper. They can be derived from Wieseman's curves for K_ϕ by means of the following formula

$$C_p = 0.636 C_1 K_\phi$$

From Figure 3, it is seen that the affect of the ratio of air gap to pole pitch, though finite, is not large and, for machines with relatively small air gaps, can be disregarded.

The simplicity of the single family of curves for C_p facilitates its use for design analysis and calculation. Comparison of calculations and test data indicates that the curves have a high degree of accuracy for the types of machines considered.

Steel Magnetizing Curves

The magnetizing force for the air gap is calculated by dividing 3.19 (the permeability of air) into the peak actual flux density of the air gap. This peak actual flux density is the value obtained by following the procedure of the design sheet and equals the ratio ϕ_r/A_g.

The magnetizing force for the teeth and core is plotted against flux density on Figure 4. These curves differ radically from the published d-c curves for the same steel because the latter do not take into account the unequal distribution of flux densities that exist in the teeth and core of an a-c generator. The usual textbook method of calculating ampere-turns is to calculate the maximum flux density in a part, determine from the published d-c

Symbols Used in Figures 1 and 2

A = effective series ampere conductors
A_g = total area of air gap
A_p = area of pole body
A_t = total area of teeth
A' = ampere conductors per inch
B' = flux density at the voltage behind the potier reactance
B_g = air gap density (air gap density at the pole center averaged over tooth pitch)
b_{tm} = tooth width half way down the teeth
b_{bar} = width of rectangular damper bar
b_h = width of pole head
b_p = width of pole
b_s = width of stator slot
b_t = width of stator tooth at tip
C_m = "demagnetizing factor" ratio of equivalent field ampere turns to maximum sine wave armature ampere turns (ratio of field to armature ampere turns for same fundamental flux)
C_p = "pole constant" ratio of average to maximum field form
C_w = winding constant
C_1 = "fundamental of field form" the ratio of the maximum fundamental to the actual maximum value of field form (figured with no saturation)
Connection = number of parallel paths, type of circuit (for example, 2-circuit Y)
D = frame bore (outer diameter of punchings)
d = stator bore
d_r = rotor diameter
d_{so} = outside spider diameter
d_{si} = inside spider diameter
E_t = rated terminal voltage
E_p = rated phase voltage
F = total no-load ampere turns
F_{dm} = demagnetizing ampere turns per pole
F_{FL} = field ampere turns at full load
F_g = air gap ampere turns per pole at rated voltage
F_g' = air gap ampere turns at $(1+X_l)\times$rated voltage
F_o = no-load ampere turns per pole
F_o' = total no-load field ampere turns at $(1+Xl)\times$rated voltage
FSC = field ampere-turns for symmetrical steady-state short circuit at rated armature current
f = rated frequency
g = single air gap
g_e = effective air gap
g_{max} = single air gap at pole tip
g_{min} = single air gap at center of pole face
h_{bar} = depth of rectangular damper bar
h_h = depth of pole head
h_p = depth of pole body
h_1 = depth of copper in slot (including insulation)
h_2 = depth of slot to the copper
I_p or I_{ph} = rated phase current
K_d = distribution factor
K_p = chord factor = sine 90 (pitch)
K_T = total flux, kilolines, in the machines the value of which would exist if density were uniform and equal to the maximum
K_z = lot chording, leakage factor
K_{1d} = damper slot reactance factor
K_1 = slot reactance factor
L_f = total field circuit inductance
l = length of stator core (including vents)
l_{et} = axial extension of diamond portion of stator winding
l_{et} = straight extension of stator and winding (average)
l_h = length of pole head including any magnetic coil supports
l_p = length of pole
l_t = depth of stator slot
MLT = mean length of turn
m = number of phases
N_p = series turns per pole on the field
n_b = number of damper bars per pole
n_e = total effective conductors
P = number of poles
q = slots per phase per pole
R_F = total field circuit resistance
r_a = armature resistance per phase
S_t = total number of stator slots (including empty)
S_ϕ = number of slots per phase
S_1 = number of stator slots used
SCR = short-circuit ratio
T_a = d-c time constant
T_d' = short-circuit transient time constant
T_{do}' = open circuit transient time constant
W = total series conductors
X = true armature leakage reactance
X_{ad} = direct axis armature magnetizing reactance
X_{aq} = quadrature-axis armature magnetizing reactance
X_d = direct-axis synchronous reactance
X_{du}' = unsaturated transient reactance
X_F' = field leakage reactance
X_l = armature leakage reactance
X_q = quadrature-axis synchronous reactance
y = number of slots spanned by the coil
Z = zig-zag leakage correction factor
α = ratio of pole arc to pole pitch
β = minimum number of poles having an integral number of slots
θ = slot skew in electrical degrees
ϕ_l = pole leakage flux
ϕ_p = total flux per pole
ϕ_r = total flux in the machine the value of which would exist if density were uniform and equal to the maximum
τ = pole pitch measured at the stator bore
τ_b = damper bar pitch (average if not uniform)
τ_r = pole pitch on rotor diameter
τ_s = stator slot pitch
λ_a = armature magnetizing permeance
λ_B = phase belt permeance
λ_b = damper bar winding permeance
λ_{Dq} = quadrature-axis damper winding permeance
λ_{Dd} = direct-axis subtransient winding permeance
λ_e = end connection permeance
λ_F = field leakage permeance
λ_{Fe} = field and leakage permeance
λ_{Fz} = field side leakage permeance
λ_l = slot permeance
λ_{pl} = pole tip damper winding

$$\lambda_f = \lambda_{f_s} + \lambda_{f_e} = 5.6$$

$$\lambda_{f_s} = 4.25\left[\frac{3(h_h + \phi - 0.058\tau_r)}{\tau_r - b_h}\right] + \frac{h_{f_1} + \frac{\tau_r}{10}\left(\frac{p-10}{p}\right) + 3h_{f2}}{\frac{\pi}{p}\,(d_r - 2h_h - 0.4h_{f_1}) - b_p}$$

$$\lambda_{f_s} = 4.25\left[\frac{3(1.46 - 0.8)}{5.4}\right] = 2.0$$

$$\lambda_{f_e} = 3.19\left[\frac{4(1h - 1) + 2h_{f_1} + 0.5\,b_p}{1}\right] = 3.6$$

DIRECT-AXIS DAMPER LEAKAGE $X_{fd}^1 = 0.0183$

(For direct-axis use dimensions of end bar near pole)

$$X_{fd}^1 = X\ \lambda_{fd} = 0.006 \times 3.04 = 0.0183$$

$$\lambda_{fd} = \left[\cos\frac{(n_h - 1)}{\tau_r}\frac{\tau_1}{2}\frac{\pi}{2}\right]\left[\frac{(h_h + h_{pt})\lambda_p}{\lambda_b + h_{pt} + h_r}\right] = \left[\cos 45\right]4.2 = 3.04$$

$$\lambda_{pt} = 6.38\left[\frac{b_h - \tau_h\,(n_h - 1)}{3d_e}\right] = 6.38\left[\frac{5.49 - 0.54}{3 \times 0.053}\right] = 2$$

$$\lambda_b = 6.38\,(X_{1d} + 0.5) = 6.38\left[\frac{.088}{.0\overline{70}} + 0.625 + 0.5\right] = 18.7$$

X_{1d} = damper slot reactance factor

QUADRATURE-AXIS DAMPER LEAKAGE $X_{fq}^1 = 0.0246$

(Use dimensions of center bars)

$$X_{fq}^1 = X\ \lambda_{fq} = 0.006 \times 4.1 = 0.0246$$

$$\lambda_{fq} = \frac{20\ \tau_b}{\tau_r}\left[\frac{h_r}{b_b} + \frac{h_{bar}}{3b_{bar}} + 0.5 + \frac{\phi}{\tau_b}\right] = \frac{18.1}{10.9} \times 2.68 = 4.1$$

$$^*\overline{\lambda} = 0.75\,\alpha^2\left[1 + \frac{98}{\lambda_a}\left(\frac{1}{\alpha^2} - 1.1\right)\right] = 0.250 \times 1.432 = 0.36$$

REACTANCES

Direct-axis synch. $X_d = X_1 + X_{md} = 0.114+2.27=2.38$

Quadrature-axis syn. $X_q = X_1 + X_{mq} = 0.114+0.906=1.12$

Unsaturated trans. $X_{1u} = X_1 + X_f^1 = 0.114+0.091=0.205$

Saturated trans. $X_1^1 = 0.68\,X_{1u} = \underline{0.18}$

steel curves, the corresponding magnetizing force in ampere-turns per inch, and to multiply this magnetizing force by the length of the magnetic path in inches. In applying this method to such a part as the core, where the flux density varies nearly sinusoidally along the length of the magnetic path, the actual magnetomotive force is the sum of the products of the magnetizing forces of each increment of the path by the length of the corresponding increment. The magnetizing force for each increment can be obtained from the d-c steel curves for the flux density prevailing in that increment.

The curves of Figure 4 were obtained for different values of maximum flux density by an averaging process. The flux densities were assumed to vary sinusoidally in accordance with the formula $B = B_{max} \sin X$, where X was increased from zero to 90 degrees in equal 5-degree increments. For each increment, the value of magnetizing current was determined from the published d-c magnetization curves for the steel and the sum was divided by the number of terms. The use of these curves has made accurate prediction of saturation curves possible where the conventional method sometimes led to ridiculous results.

Figure 3. Peak fundamental and average of no-load flux wave

Core Loss

A rough estimate of the no-load iron losses for teeth and core can be obtained from the following equation

$$\text{Core loss in watts} = 5W(WL)\left(\frac{B}{100}\right)^2\left(\frac{f}{60}\right)^{1.4}$$

where

W = weight of part (core or teeth)
B = maximum flux density in part (kilolines per square inch)
f = fundamental frequency in part (cycles per second)
(WL) = watts per pound guaranteed by the manufacturer at 10,000 gauss, 60 cycles per second, for the grade and thickness of the steel laminations used

For a more accurate calculation, Spooner's method[4,5,6] can be used.

Slot Factor K_1

The slot factor K_1 is the permeance of the slot leakage path and the formulas are given in numerous text books and technical papers. Using the nomenclature of the design sheet, the value can be obtained for a rectangular semienclosed slot by the formula

$$K_1 = \frac{d_1}{b_1} + \frac{2d_2}{b_1+b_2} + \frac{d_3}{3b_2}$$

The permeance of a circular slot with an opening of normal size at the top is

$$K_1 = \frac{d_1}{b_1} + 0.625$$

The permeance of a semicircular slot bottom is equal to 0.14, so that for a semienclosed rectangular slot with semicircular bottom

$$K_1 = \frac{d_1}{b_1} + \frac{2d_2}{b_1+b_2} + \frac{d_3}{3b_2} + 0.14$$

Chording Leakage Factor, K_2

The chording leakage factor is given in Figure 1 of Kilgore's[1] article, Figure 2 of Alger's[7] article, and in Figure 143, page 219 of Kuhlmann's design text.[8]

Discussion

The design method outlined takes into account only the performance characteristics of the machine but does not attempt to evaluate losses or heat dissipation factors accurately. This was done partly because of the fact that no method is known for the accurate predetermination of temperature rises and partly because for the generators under consideration, the design will usually be dictated by performance rather than by temperature rise. This condition will become increasingly true as the use of high-temperature insulation becomes more prevalent. For the present, some indication of reasonable temperature rises is afforded by using such criteria as d^2l, current densities, ampere-conductors per inch of periphery, and cooling air velocities. For the machines in question, the values of d^2l, can be assumed to be proportional to $(kw/rpm)^{0.64}$.

In basing the design on transient performance, suitable criteria had to be established. An important criterion was the ability of the generator to start and accelerate motors. To prevent stalling of motors and opening of contactors during the accelerating period, it is necessary that the minimum rms voltage of the

generator, as determined by oscillograph, should not drop to less than 70 per cent of rated voltage. It also is necessary that during the accelerating period, after the automatic voltage regulator action has stabilized, the generator voltage should be at least 80 per cent of rated voltage. These values are based on drop-out voltage of 65 per cent for magnetic contactors and a pull-out torque of 200 per cent for induction motors. At 70 per cent voltage the pull-out torque is 128 per cent, leaving some margin for acceleration when driving a load having constant torque characteristics.

The following equation is used for determining the minimum transient rms voltage in per unit

$$E_{min} = \frac{Z_L}{Z_L + X_d} + \left(\frac{Z_L}{Z_L + X_d'} - \frac{Z_L}{Z_L + X_d}\right) e^{-t/T'_{d1}}$$

where

Z_L = impedance of starting motor in per unit
X_d = direct axis synchronous reactance
X_d' = transient reactance of generator in per unit
t = response time for regulator (0.1 second for most mechanical regulators)
T_{d1}' = generator time constant for load Z_L
T_{do}' = generator open-circuit time constant

$$T_{d1}' = T_{do}' \frac{Z_L + X_d'}{Z_L + X_d}$$

Further work is necessary in order to generalize the effects of machine dimensions on the flux in the interpolar spaces. This would make it possible to calculate field harmonics accurately without resorting to laborious flux plotting for each new generator design.

The leakage factor X_p', used in Figures 1 and 2 is calculated in accordance with the formulas of Kilgore.[1] It is correct only for the determination of transient reactance since it evaluates the linkages of the leakage flux with the field winding rather than the total leakage flux. However, the value X_p' has been used in the design sheets to calculate total leakage flux. The results obtained so far do not appear to require a separate calculation for total leakage flux.

In calculating full-load and zero-power-factor ampere-turns the factor $(1+X_p')$, was used to make some allowance for the increase in ampere-turns of the field pole because of the increase of leakage flux resulting from the component of field required to neutralize the armature demagnetizing action.

Appendix I. Derivation of Equations for C_1

The field form at no load has no even harmonics, it is symmetrical with respect to the origin of co-ordinates, and the fundamental component can therefore be expressed by: (Refer to Figure 5)

$$C_1 = \frac{B_1}{B_m} = \frac{g_n}{3.19\ NI} \times \frac{4}{\pi} \times 3.19\ NI \int_0^{\pi/2} \frac{\cos\phi\, d\phi}{g} = \frac{4g_n}{\pi} \int_0^{\pi/2} \frac{\cos\phi\, d\phi}{g}$$

Assuming the effect of flux in the interpolar spaces to be negligible

$$\int_0^{\pi/2} \frac{\cos\phi\, d\phi}{g} = \int_0^{\alpha\pi/2} \frac{\cos\phi\, d\phi}{g}$$

For a uniform air gap

$$C_1 = \frac{4g_n}{\pi}\left[\frac{\sin\phi}{g}\right]_0^{\alpha\pi/2} = 1.27 \sin\frac{\alpha\pi}{2}$$

For the air gap shown in Figure 5

$$C_1 = \frac{4g_n}{\pi} \int_0^{\alpha\pi/2} \frac{\cos\phi\, d\phi}{g} = \frac{4g_n}{\pi} \times \int_0^{\alpha\pi/2} \frac{\cos\phi\, d\phi}{g_n + \left(\frac{g_x - g_n}{\sin^2\frac{\alpha\pi}{2}}\right)\sin^2\phi}$$

$$C_1 = 1.27 \int_0^{\alpha\pi/2} \times \frac{\cos\phi\, d\phi}{1 + \left(\frac{g_x}{g_n} - 1\right)\left(\frac{1}{\sin^2\frac{\alpha\pi}{2}}\right)\sin^2\phi}$$

Figure 4. Magnetizing curves for steel, showing the effect of sinusoidal distribution of flux density

$$C_1 = 1.27\left[\sqrt{\left(\frac{g_x}{g_n} - 1\right)\left(\frac{1}{\sin^2\frac{\alpha\pi}{2}}\right)}\right] \times \tan^{-1}\left[\sin\frac{\alpha\pi}{2}\sqrt{\frac{\frac{g_x}{g_n} - 1}{\sin^2\frac{\alpha\pi}{2}}}\right]$$

$$C_1 = 1.27 \sin\frac{\alpha\pi}{2} \frac{\tan^{-1}\sqrt{\frac{g_x}{g_n} - 1}}{\sqrt{\frac{g_x}{g_n} - 1}}$$

Appendix II. Derivation of Equation for C_p

C_p is the average value of flux density divided by the maximum value of flux

Figure 5. Length of air gap as a function of pole shape and angular displacement from pole center

g_n = Minimum gap
g_x = Maximum gap
g = gap at any point
R = Radius of stator bore
r = Radius of pole face
H = Offset of center of pole face arc from center of stator circle
α = Pole embrace
ϕ = Angular position of point with gap "g" with respect to center of pole

$$g = R - H\cos\phi - \sqrt{r^2 - H^2\sin^2\phi}$$
$$g_n = R - H - r$$
$$A = R - r - g_n$$
$$g_x = R - H\cos\frac{\alpha\pi}{2} - \sqrt{r^2 - H^2\sin^2\frac{\alpha\pi}{2}}$$
$$\sqrt{r^2 - H^2\sin^2\phi} \approx r\left(1 - \frac{H^2\sin^2\phi}{2r^2}\right)$$
$$H\cos\phi - H\sqrt{1 - \sin^2\phi} = H\left(1 - \frac{1}{2}\sin^2\phi\right)$$
$$g \approx (R - H - r) + \frac{1}{2r}(H^2 + HI)\sin^2\phi$$
$$g \approx g_n + \frac{1}{2r}(H^2 + HI)\sin^2\phi$$
$$g_x \approx g_n + \frac{1}{2r}(H^2 + HI)\sin^2\frac{\alpha\pi}{2}$$
$$\frac{1}{2r}(H^2 + HI) = \frac{g_x - g_n}{\sin^2\frac{\alpha\pi}{2}}$$

density. The average value of flux density is the total flux under the pole divided by the area under the pole pitch. Assuming that the flux density at any point is inversely proportional to the air gap at that point, and neglecting the flux in the interpolar spaces: (See Figure 5)

$$B_{max} = \frac{3.19\ NI}{g_n}$$

$$B_{av} = \frac{\phi_p}{\text{pole area}} = \frac{2}{1R\pi}\int_0^{\pi/2} BdA = \frac{2}{1R\pi}\times \int_0^{\alpha\pi/2} \frac{3.19\ NI\ 1Rd\phi}{g}$$

$$B_{av} = \frac{2}{\pi}\times 3.19\int_0^{\alpha\pi/2}\frac{d\phi}{g}$$

$$C_p = \frac{B_{av}}{B_{max}} = \frac{2}{\pi}\frac{g_n}{}\int_0^{\alpha\pi/2}\frac{d\phi}{g}$$

For a uniform gap

$$C_p = \frac{2}{\pi}\frac{g_n}{}\frac{\frac{\pi}{2}\alpha}{g_n} = \alpha$$

For the gap shown on Figure 5

$$C_p = \frac{2}{\pi}\int_0^{\alpha\pi/2}\frac{d\phi}{1+\left(\frac{g_x}{g_n}-1\right)\frac{1}{\sin^2\frac{\alpha\pi}{2}}\sin^2\phi}$$

The integral is of the form

$$\frac{1}{2}\int\frac{d(2\phi)}{\left(1+\frac{a^2}{2}\right)-\frac{a^2}{2}\cos 2\phi}$$

$$C_p = \frac{0.636\sin\frac{\alpha\pi}{2}}{\sqrt{\frac{g_x}{g_n}-1+\sin^2\frac{\alpha\pi}{2}}}\times \tan^{-1}\left[\frac{\frac{g_x}{g_n}-1+\sin^2\frac{\alpha\pi}{2}\left(\tan\frac{\alpha\pi}{2}\right)}{\sin\frac{\alpha\pi}{2}}\right]$$

$$C_p = 0.636\tan\frac{\alpha\pi}{2}\times \frac{\tan^{-1}\sqrt{\frac{g_x/g_n}{\cos^2\frac{\alpha\pi}{2}}-1}}{\sqrt{\frac{g_x/g_n}{\cos^2\frac{\alpha\pi}{2}}-1}}$$

Discussion

Paul W. Franklin (Bendix Aviation Corporation, Teterboro, N. J.): Mr. Ginsberg is to be congratulated for his publication, which regrettably is one of the few papers dealing with actual design calculations. Whereas there is no lack in the number of theoretical papers, actual design methods are rarely published and thus the average designer cannot always benefit from the advances of theory.

Mr. Ginsberg developed his paper for the design of light-weight minimum-size machinery for the Armed Forces. It is of interest to note that for aircraft this type of equipment was required and produced years ago. The specifications as to weight, bulk, and performance are difficult to attain. This led to the development of a special line of rotating equipment, the performance of which indicates that sooner or later the principles and procedure employed will be adopted by manufacturers, wherever light-weight minimum size equipment is essential.

The design of minimum size equipment was made possible by the use of Silicone varnish, inorganic insulation, high strength materials, and to a certain extent by the development of practical power selenium rectifiers. The use of Silicone varnish permitted a design which was not limited by temperature. High strength materials permitted speeds of 24,000 rpm and more for comparatively large ratings and selenium rectifiers permit the use of transductors and may, to a certain extent, replace the commutator on d-c generators.

The theory, used for these designs is of course the same as for commercial machines, except that it is refined and specialized to a very high degree. In order to get the most out of a certain amount of material, a good designer cannot use commercial proportions, density data and empirical curves, but must be prepared to rederive and modify his formulas, for example, leakage flux and reactance formulas, as his design proceeds.

Mr. Ginsberg states that the customary methods to calculate the saturation curves are insufficient. In minimum size machines, the actual physical flux, that is, air gap flux plus local leakage flux, must be calculated closely to permit the use of high magnetic densities without resulting oversaturation. Local saturation around slots carrying high currents should be checked. Depression of the originally sinusoidal air gap flux due to tooth saturation occurs, but can be approximated. The ampere turns required to drive the flux through the yoke are usually much less than obtained by commercial formulas and may be obtained either as Mr. Ginsberg indicates, or by using the results of investigations published. In the same way, the pole-to-pole leakage flux formulas for commercial design must be disregarded and each case should be calculated on its own merits. Direct and quadrature axis coefficients become a function of the saturation in the vicinity of the air gap and a field weakening occurs, due to flux distortion under load, similar to the uncompensated d-c machine.

All these points of consideration complicate the design work to a great extent, but on the other hand permit the design of a light-weight machine where each dimension is reduced to the minimum and where each component carries just as much as it can and not more. The result of this is that today 400-cycle machines can be built, with magnetic densities determined entirely by saturation and not by temperature, and that often with a 100 per cent overload capacity. Copper densities have been increased two to four times that of commercial machines without detriment to a reasonable lifetime.

It appears to the writer, that the designer of such equipment must be well versed in theory and rather unprejudiced by commercial design methods. He should discard empirical curves and semiempirical formulas and take nothing for granted. Under these conditions a design sheet serves only as a neat record for final design data, but by no means as a method.

R. C. Powers (Electric Machinery Manufacturing Company, Minneapolis, Minn.): Although Mr. Ginsberg's paper presents no new concepts in the design of a-c generators, it does present a simplified procedure for designing such machinery. The design sheet itself is laid out in such a way that a complete picture of a machine can be had with little more than a glance and the performance can be determined quite readily.

In the introduction of this paper, the author has stressed the importance of establishing criteria for the design and performance of relatively small a-c generators. In developing the steel magnetization curves (Figure 4), the flux densities were assumed to vary sinusoidally. In small machines of the salient-pole type, however, where the ratios of air gap length to pole pitch are relatively small and where the flux densities are relatively high, the flux wave departs greatly from a sine wave. Test oscillograms have proved such waves to approach a squared condition. In

$$\left[\frac{1+0.6(X_{ag}+X_{ad})+X_{ag}X_{ad}}{\sqrt{1+1.2\,X_{ag}+X_{ag}^2}}-1\right]\left[1+X_F'\right]F_g$$

Figure 1

determining the constants C_1 and C_p from these oscillograms, however, they, too, differed from those obtained from curves included in this paper (Figure 3). Tests indicate that these differences occur in such a way that, if C_1 and C_p are determined from Figure 3 and a sine wave of flux is assumed in obtaining the flux density–field intensity curves, the end results (magnetizing forces) are substantially the same as when C_1, C_p, and the flux wave form are obtained from oscillograms.

About the time the material was being prepared for this paper, an independent investigation was being conducted for the purpose of obtaining reliable stator magnetization curves. The flux wave was analyzed by the same method as Mr. Ginsberg describes in this paper with the exception that an oscillogram of an actual air gap flux wave was used for analysis instead of a pure sine wave of flux. The flux density–field intensity curves resulting from this investigation were effectively identical with those of Figure 4 of the paper. However, these curves proved to be too optimistic when applied to analyses of machines already in existence and tested; that is, the curves indicated excessively high effective iron permeabilities.

Therefore, a new approach was used to determine reliable magnetization curves. The total magnetomotive forces at various inductions were determined by test for several machines using 29 gauge, 0.72 watt-loss steel. The air gap magnetomotive forces were calculated, and the pole and spider magnetomotive forces determined from manufacturer's d-c magnetization curves at these inductions. The tooth and core flux densities were calculated at the corresponding inductions. Tooth and core magnetization curves were then plotted in such a way as to provide stator magnetomotive forces so that the total calculated machine magnetomotive forces met the test values of total magnetomotive force at all inductions. These flux density–field intensity curves for all machines effectively coincided with one another to result in a single curve for 29 gauge, 0.72 watt-loss steel. Test results of additional machines designed in accordance with the design sheets (Figures 1 and 2) of this paper and by the use of this curve met the calculated performance estimates very closely in all cases. This curve indicates lower effective permeabilities than those indicated by Figure 4 of this paper but higher effective permeabilities than those indicated by manufacturers' d-c magnetization curves at corresponding inductions. Stator flux density–field intensity curves for grades of steel other than 29 gauge, 0.72 watt-loss can be interpolated from this curve and the proper manufacturers' d-c magnetization curve.

As expressed in this paper, there is a present demand for small light-weight a-c generators. The trend is toward higher flux densities, and, in order to maintain optimum electric and magnetic balances, the current densities become correspondingly higher. Recent developments in high temperature materials and high permeability electric steels have made such machines more practical from an economy standpoint. In high temperature a-c generators having good transient performance, armature resistance becomes increasingly effective; it may become as much as 250 per cent and more of the armature leakage reactance. In calculating the short-circuit ratio, reactances, and load excitations of a machine (refer to Figures 1 and 2), therefore, armature resistance cannot be ignored.

The author's expression for full load excitation at 0.8 power factor (Figure 1) should be modified slightly:

$$F_{FL}=\left[\frac{1+0.6(X_{ag}+X_{ad})+X_{ag}X_{ad}}{\sqrt{1+1.2X_{ag}+X_{ag}^2}}-1\right]\times[1+X_F']F_g+F_o'[1\times X_F']$$

This expression is evident from test results, and from Figure 1 of this discussion.

E. R. Martin (University of Michigan, Ann Arbor, Mich.): The importance of transient factors on a small single-phase generator would appear to be relatively unimportant, and it is unfortunate that a 3-phase design was not used to illustrate the calculations.

The design itself is not according to usual practice. The stator has 27 slots which makes the winding unsymmetrical. A lap winding is used while a concentric winding would give better wave shape and use about 14 per cent less copper. The rotor is evidently of special construction, since the pole dimensions leave no room for a shaft, so the revolving field must be supported between nonmagnetic rings with stub shafts attached, which is expensive construction and not very satisfactory. In this case there is no spider, contrary to calculations shown. The core density is higher than the tooth density while the reverse is generally used. The teeth are tapered, being wider near the air gap which makes it appear that a slot die was used which was made for another machine. The test value of core loss was not given in Table I, and that is one item that is difficult to calculate.

A good 3-phase design would have made a much better foundation for the calculations.

David Ginsberg: Mr. Franklin's discussion emphasizes the importance of returning to fundamental principles of design and discourages the use of empirical formulas. The author heartily agrees with this philosophy and hopes that he will find the opportunity to describe these methods more fully. It would be interesting to compare the calculation of one of Mr. Franklin's generators by means of the methods presented in this paper with a calculation by Mr. Franklin's method. The need for a better knowledge of flux densities in the useful and leakage paths is recognized. In a recent conversation with Mr. Wieseman of the General Electric Company, the author learned that Mr. Wieseman has developed a machine for making 2-dimensional and 3-dimensional flux plots.

Mr. Franklin seems to have overlooked one important application of the proposed design method. To the extent that the paper has adhered closely to formulas rigorously derived from fundamental principles, the design sheets are much more useful than a mere record for final design data. The orderly array of the formulas and curves provide a clear indication of the effect of the various design parameters on generator performance and facilitate the selection of these parameters in accordance with actual limitations rather than average practice.

Mr. Powers makes a number of significant points which call for specific answers. As he correctly points out, the stator magnetization curves were based on a sinusoidal distribution of flux density, although a discontinuous linear distribution (for a perfectly flat flux wave) would be more nearly correct for many generators. While the theoretical validity of this argument has been realized, it is pointed out that the exact equation of flux distribution is relatively unimportant providing the differences between actual and sine wave flux densities are confined mainly to the unsaturated portion of magnetic circuit where the differences in the required magnetomotive forces are negligibly small. In the saturated portions of the magnetic circuit, the sine wave approximation is quite close and results on actual machines have borne this out. The experimental investigation of stator magnetization curves and field form coefficients referred to by Mr. Powers was made at the writer's suggestion in the course of a Government development contract with the Electric Machinery Manufacturing Company. At that time stator magnetization curves had been calculated for electrical grade steel only and it is not surprising that the ampere-turn values were optimistic compared to Mr. Powers' test data made with 0.72 watt-loss steel. A theoretical stator magnetization curve for 0.72 watt-loss steel has since been calculated and is compared in the following table with Mr. Powers' curve embodied in a report to the Engineer Research and Development Laboratories.

Flux density (kilolines)	.95	.105	.115	.120	.125	
Mmf by Powers' test data	.36	.64	.118	.168	.240	
Mmf from calculated curve	.25	.60	.118	.165	.250	

As Mr. Powers points out, his data were obtained for machines with an almost rectangular flux wave and for a very small pole embrace, yet the agreement between

test and calculated curves is well within the limit of experimental error. The alternative implied by Mr. Powers' discussion is to have separate magnetization curves for every conceivable pole-shoe and air gap configuration. The writer believes that this would be a step backward.

Mr. Powers is correct in stating that the voltage drop due to armature resistance cannot be ignored in concentrated machines operated at high temperatures. This factor has been taken into account in the formula for full-load field excitation by basing it on the stator flux required to generate the arithmetic sum of the terminal voltage plus the leakage reactance drop instead of the vector sum of these two quantities. Assuming the stator resistance to be of the same order of magnitude as the leakage reactance, this takes the resistance into account and simplifies the calculation.

Mr. Powers implies that his proposed equation corrects a theoretical mathematical error in the writer's formula. It appears that his proposed formula contains typographical errors. For example, the subscript "ag" should be "aq" and the factor "$1 + F'''$" should apparently be a leakage drop factor such as "$1 + X_1$." Taking these obvious corrections for granted, Mr. Powers' formula would be theoretically more correct than that in the paper if he had not overlooked a very important physical phenomenon. This phenomenon involves the effect of armature reaction on the pole leakage flux. At a no-load per-unit voltage of $1 + X_1$ the pole body flux density is the corresponding value of B' in the design sheet. However, at full load the pole leakage increases in proportion to the following quotient: stator plus gap plus armature reaction ampere-turns divided by stator plus gap ampere-turns. This increases the pole-body flux density and magnetomotive force. It is a very large factor where the pole bodies are highly saturated. By rigorous mathematical standards the writer's formula for full-load 0.80 power factor is incorrect but it is relatively simple and contains compensating errors which take account of the increased pole leakage under load. Its accuracy may be estimated by reference to Table I of the paper. Since the paper was written, the writer has applied his method to the design of a number of 50-cycle, 60-cycle, and 400-cycle machines which have since been built and tested. The accuracy of the full-load and no-load field currents have been within 4 per cent of the predicted values even though the designs covered a wide range of ratings and extreme differences in magnetic saturation. It also has been found by mathematical analysis that the expression for field excitation can be still further simplified with negligible loss of accuracy. The simplified formula is:

$$F_{FL} = [0.90F_g(1+X_d)+F_a'-F_g'][1+X_F']$$

Mr. Martin questions the importance of transient factors on small single-phase generators and raises several questions concerning the construction of the machine used as an illustrative example of the design method.

Transient response is very important for small generators since they are frequently called upon to start and accelerate motors whose locked-rotor current may be more than twice the rated current of the generator. The need for good transient response has been borne out by military experience. It also should be noted that some of the transient characteristics are used for the accurate calculation of steady-state values. This is particularly true of single-phase machines in which negative-sequence impedance determines steady-state characteristics. The 27-slot winding is not unsymmetrical but is a typical fractional slot winding so chosen as to permit the elimination of multiples of the third harmonic. The rotor of this machine actually does have a shaft and the term "spider," used in the calculations, refers to that portion of the magnetic circuit of the rotor which is located between the poles. The fact that the pole density is greater than the tooth density and that "the reverse is generally used" is of minor importance compared with the attainment of design goals. Mr. Franklin's discussion has clearly explained the fallacy of blind adherence to custom. Slot dies are normally used for a large number of machines and are not usually allocated to any specific machine. The slot die used on the generator calculated in the design sheets is one of the standard dies used by a prominent manufacturer and was selected as being the most suitable available die. The actual open-circuit core loss on this generator was 105 watts at rated volts.

A small single-phase generator was deliberately chosen for illustrative purposes to show that the proposed design method applies even to these machines which have been ignored by the literature.

Several oral discussions also were made at the meeting, and the author takes this opportunity to answer them.

Mr. W. R. Hough of the Reliance Electric and Manufacturing Company expressed an interest in d-c generator design calculations similar to those for a-c generators presented in this paper. Such d-c generator design calculations have been incorporated by the writer into a design sheet which has been used with some success at the Engineer Research and Development Laboratories for about one year. Publication of the d-c generator design calculations has been withheld until the method has been substantiated by sufficient experience with actual machines.

The suggestion of Sterling Beckwith of the Allis-Chalmers Manufacturing Company to express the magnetomotive forces of the magnetic circuit in per-unit values is a novel one and appears to present an opportunity for broadening the value of design data on specific machines.

The approval of this paper by Mr. L. A. Kilgore of the Westinghouse Electric Corporation is particularly gratifying since his paper of 1931[1] furnished much of the background for the present paper. His comments concerning the need for a synthetic design method are encouraging. As stated in my paper, considerable work has already been done toward this goal. The initial equations are set up to solve for generator dimensions in terms of desired values of generator weight, electrical output, transient reactance, and square inches per watt of heat dissipating surface. A number of simplified analytical expressions have been derived to make this approach practical. For example, the constant C_1 can be calculated from the formula:

$$C_1 = 1.27\left(\frac{g_2}{g_n}\right)^{-0.35} \text{Sin } (90\times\text{pole embrace})$$

Certain attitudes toward accurate equations expressed in the paper and in the foregoing discussions may seem contradictory but they are actually consistent. In striving toward a synthetic design method which could be used for development, no attempt was made to simplify the equations by assuming factors based on customary design procedure or by ignoring factors which are negligible only in conventional machines. A high degree of accuracy even for unconventional designs is necessary if safety factors are to be reduced to a bare minimum. On the other hand, every effort was made to eliminate complicated expressions whose only justification was their mathematical rigor.

Aircraft D-C Circuit Breakers for 28 and 120 Volts

B. S. BEALL, III
ASSOCIATE AIEE

P. J. REIFSCHNEIDER
ASSOCIATE AIEE

Synopsis: The electric systems of many modern airplanes, particularly the generator circuits of multiengined airplanes, are being operated without adequate electrical operation. This practice is quite different from that usually followed in other electric systems. To provide the necessary protection, new aircraft circuit breakers have been developed with ratings of 300 and 600 amperes at 28 volts and 250 amperes at 120 volts. The interrupting ratings, over a range of altitude from sea level to 50,000 feet, are 12,000 amperes and 5,000 amperes for the 28- and 120-volt circuit breakers respectively. A compact and efficient interrupter makes the 120-volt rating possible. For generator circuit applications, an inverse time-delay reverse-current trip device has been designed for the circuit breakers. For other applications, nondirectional time delay and directional and nondirectional instantaneous trip devices have been designed. Trip-free mechanisms for both the manually and electrically closed circuit breakers and antipump control for the closing solenoid add to the protection provided by these circuit breakers. The operation of these circuit breakers is satisfactory under conditions of vibration, shock, sand and dust, and extremes of temperature and humidity, incident to aircraft.

THE electric systems of airplanes, both commercial and military, are increasing continually in size, complexity, and importance to the over-all operation. To insure the safety of persons in flight and to safeguard equipment, generators and their associated circuits, feeder circuits and load circuits should all be protected. Circuit breakers with adequate continuous current and interrupting capacity, trip-free mechanisms, manually and electrically closed, and with suitable fault sensing elements, offer the best means of protection.

A circuit breaker is primarily a protective device and to be reliable must be free from contact welding, provide fast fault interruption, and have positive and accurate time-current tripping characteristics. Recently, new single-pole d-c aircraft circuit breakers have been developed which meet present and anticipated future requirements. The ratings, size, and weights of these circuit breakers are shown in Table I.

Either directional or nondirectional trip devices with instantaneous or inverse time characteristics can be incorporated in these circuit breakers. The selection of the type of trip device and its setting depends upon the application of the circuit breaker in the electric system.

Application

The most important application for the recently developed circuit breakers is in generator circuits of multiengined airplanes. In the electric system of a 4-engined airplane, as many as six generator circuits may be connected in parallel to the bus.

A typical generator circuit, including a reverse-current circuit breaker and a generator relay, is shown in Figure 1(A). The generator relay consists of a contactor and a pilot relay. When the generator voltage exceeds the bus voltage, indicating that the generator can supply current to the bus, the contactor closes. When the generator voltage falls below the bus voltage, the reverse flow of current from the bus to the generator causes the contactor to open. For these normal switching operations, the generator relay is adequate. However, under fault conditions in the generator circuit, the generator relay may not be able to clear the circuit because of its limited interrupting capacity. A circuit breaker with adequate interrupting capacity is required to quickly and safely remove the faulted generator circuit from the bus. System tests and operating experience indicate that only circuit breakers with suitable tripping elements provide the needed protection.

Table I. Ratings, Size, and Weights

Voltage Rating, Volts D-C	Continuous Current Rating, Amperes	Interrupting Rating, Amperes (Sea Level to 50,000-foot Altitude)	Size: Width, Depth, and Height, Inches	Weight, Pounds
28	300	12,000	$2^1/_2$ by $4^{27}/_{32}$ by $8^1/_2$	4.5
28	600	12,000	$2^1/_2$ by $4^{27}/_{32}$ by $8^1/_2$	5
120	250	5,000	$2^1/_2$ by $4^{27}/_{32}$ by $8^1/_2$	4.5

To properly protect the generator circuit and to provide adequate back-up protection for the reverse current relay, the circuit breaker should have the following time-current characteristics:

1. Ultimate trip between 150–200 amperes.
2. Delayed tripping time of 60 to 100 milliseconds at 700 amperes.
3. Instantaneous tripping time not in excess of 20 milliseconds at 2,000 amperes and above.

Reverse-current circuit breakers having different time-current characteristics from those described above can be applied, as shown in Figure 1(B), in dual channel feeders. In this application, the directional circuit breakers near the load trip instantly when current flows from the load bus into the feeder. The circuit breakers located at the source bus are equipped with nondirectional overcurrent trip devices.

For other applications such as bus sectionalizing, single feeder circuits and load circuits, the circuit breakers are equipped with nondirectional overcurrent trips in place of the reverse current devices. For remote tripping in any application, the shunt device may be energized by a relay or other means.

General Description

Figure 2 shows a manually-closed circuit breaker and Figure 3, an electrically-closed circuit breaker. All ratings of the manually-closed circuit breaker are identical in size and outward appearance. The weight of the 600-ampere rating is slightly greater than that of the two lower current ratings because of the greater cross section of the current carrying parts. The addition of the closing solenoid increases the weight of the circuit breaker by two pounds and the depth by two inches.

The general arrangement of the circuit breaker is shown on the right in Figure 2. For the purpose of illustration, one side frame of the mechanism has been made of transparent material. The trip devices (9, 10, 11, and 12) are located at the top of the circuit breaker above the operating mechanism. The circuit breaker contacts are completely enclosed in the interrupting chamber in the base and therefore are not visible in this figure.

Interrupter

The interrupter of the 28-volt circuit breaker contains a simple bridge contact structure shown in Figure 4. The moving contact is made of two parallel copper bridge members. When the circuit breaker is closed, this contact completes the circuit between the two stationary copper connecting bars. The contact tips, both moving and stationary, are made of arc-resistant silver tungsten carbide material. Experience has shown that this material provides long contact life

and is free from welding. The contacts are assembled in the interrupting chamber in the circuit breaker base which is closed by an insulating sheet. This sheet and the base are made of highly arc-resistant material.

A pressure of about seven pounds per pair of contact tips, provided by the contact spring, is ample to maintain the temperature rise of the contacts within desired limits. The two parallel bridge members provide sufficient conducting cross-sectional area for the maximum rating of 600 amperes.

Two advantages are gained in using a bridge-type contact instead of a hinge construction: flexible connections are unnecessary, and considerable blowout effect is obtained without coils or permanent magnets. The current path through the contact structure is such as to cause the arc to loop outward from each end of the bridge member when the contacts part. The arc is extinguished quickly due to the voltage drops in the lengthened arc path and the two cathodes in the double break interrupter. In a 28 volt interrupter, the two cathode drops constitute a large percentage of the total system voltage, making interruption relatively easy. The performance of this 28-volt interrupter is virtually unaffected by altitudes as high as 50,000 feet, up to its interrupting rating of 12,000 amperes.

The problems of developing a d-c interrupter for high altitude duty are much more difficult at 120 volts than at 28 volts. It is likely that this difficulty has delayed the development of the 120-volt aircraft electric system. Although interruption is not entirely a function of the dielectric strength of the medium surrounding the contacts, it is in some measure proportional to it. The curve of the dielectric strength of air at various absolute pressures shown in Figure 5 extends over a range from 1.7 pounds per square inch, which represents an altitude of 50,000 feet, to 100 pounds per square inch. This curve shows that air is a relatively poor insulator at high altitudes and that its insulating properties improve rapidly with increasing pressure. This characteristic suggests that interruption can be accomplished quickly by allowing the arc to generate its own pressure and raise the dielectric strength of the gas surrounding the contacts.

Experience has shown that hard white vulcanized fiber, specially prepared for interrupters, is an excellent material for producing gas and does not deposit sufficient carbon to cause tracking. The interrupter which was designed for the 120-volt circuit breakers, contains this type of fiber. The gases evolved are permitted to build up the pressure in a tight enclosure, helping considerably to extinguish the arc and withstand the recovery voltage.

A skeleton view of the essential parts of the 120-volt interrupter is shown in Figure 6. These parts are supported in a recess in the phenolic asbestos base which forms the enclosure for the interrupter. The bridging contact provides a double break, total of three-quarters of an inch, and like the contact structure in the 28-volt interrupter, eliminates the necessity for flexible braids. Closely surrounding the movable and stationary contact tips, and extending upward for slightly more than the length of the breaks, are two fiber tubes. At current levels above approximately 1,000 amperes, there is sufficient blowout effect from the contact configuration to drive the arcs against the inner surfaces of the tubes. Below 1,000 amperes, the steel half tubes around the fiber tubes help to draw the arcs against the fiber. As the contacts reach the fully open position, a valve (4) on the operating rod (5) closes against a valve seat molded in the base to seal the top of the interrupter enclosure. The bottom of the enclosure is effectively sealed.

The performance of this compact and efficient interrupter is shown graphically in Figure 7. The family of arcing time versus current curves at altitudes up to 50,000 feet shows that over a range of currents up to 5,000 amperes, the maximum arcing time is 32 milliseconds.

Operating Mechanism

The break distance and contact pressure required by the interrupter establish a starting point for the design of a circuit-breaker mechanism. Bridging contacts, such as are used in these circuit breakers, must be operated in a straight line. The required motion and contact pressure are obtained from a conventional latched, over-center toggle mechanism. The mechanism is tripped when the trip devices release the latch. Two strong springs snap the contacts to the open position.

To close the mechanism manually, pressure is exerted on the closing lever

Figure 5 (left). Breakdown voltage—absolute pressure for air with 3/8 inch diameter, electrodes 3/8 inch apart

Figure 7 (right). Arcing time versus current at altitudes from sea level to 50,000 feet for the 120-volt interrupter

Figure 8. Control circuit for electrically-closed circuit breaker

of the circuit breaker toward the base. The required pressure may easily be applied with the heel of the hand. In the electrically-operated circuit breaker, the solenoid exerts the required force on the closing lever extension, (1) in Figure 3.

One of the outstanding features of this mechanism and one that makes it different from earlier aircraft circuit-breaker mechanisms is that it is trip free. By trip free it is meant that the contacts are able to open fully and quickly if the circuit breaker is tripped while the mechanism is in the process of being closed or while the mechanism is held in the closed position. With this type of mechanism, it is impossible for the operator to maintain power flow into a fault.

Closing Solenoid

In order to conserve space, circuit-breaker closing solenoids usually are designed with a very short time rating and must be energized only momentarily. To protect the coil against overheating, some automatic means should be provided of de-energizing the coil after the solenoid has closed the circuit breaker. It is not good practice to rely on momentary contact control switches which depend entirely on the judgment of the operator to determine the length of time the coil should be energized.

For the protection of the circuit breaker and the system to which it is connected, the control circuit for the solenoid should be antipump. Antipump signifies that the closing solenoid will make but one attempt to close the circuit breaker each time the solenoid is energized.

To keep the size and weight to a minimum and to produce an antipump control circuit, a 2-winding coil is used in the solenoid. The two windings are connected in series with a short-circuiting switch across the high-resistance winding, as shown in the schematic circuit diagram, Figure 8. When the solenoid plunger comes to the end of its stroke, the short-circuiting switch, (2) in Figure 3, is opened and both windings are placed in series. The plunger is held in this position at the end of its stroke until the closing switch is opened. Should the circuit breaker trip while the solenoid is energized, it can not reclose until the operator intentionally opens and recloses the closing switch.

Trip Devices

For generator circuit applications two trip devices ordinarily are used, the shunt trip and the time-delay reverse-current trip. The shunt trip device makes possible remote tripping over a wide range of system voltage. To protect the coil against overheating, one of the auxiliary switches, (5) shown in Figure 2, is connected in series with the shunt trip coil as shown in Figure 8. As the circuit breaker trips, this switch opens and de-energizes the coil. Closing the circuit breaker closes the auxiliary switch and automatically sets up the trip circuit.

The time-delay reverse-current trip device consists of two elements, the time-delay escapement mechanism, 1, 2, and 11 through 14 in Figure 9(A), and the magnetic circuit comprising the field and moving armature. These elements are shown separated from each other in Figure 9(A), and in their normal assembled positions in Figure 9(B). The armature, (10), the center position of which is a permanent magnet, is supported in pivots between the pole pieces, (4) and (7) of the field structure. The single-turn series coil, (9), loops through the yoke, (8), and passes over the top of the armature.

With forward direction current or no current in the series coil, the armature seeks the normal position of Figure 9(A). When the current in the series coil reverses, the armature moves to the tripped position of Figure 9(B). As it moves, the armature releases the latch of the circuit breaker mechanism. These actions of the armature, in response to either forward or reverse direction current, occur because the armature at all times seeks the position that offers the path of least reluctance for its flux. A reset lever actuated by the opening of the circuit breaker mechanism returns the armature from the tripped position back to the normal position.

In either the normal position with forward current in the series coil, or the tripped position with reverse current in the coil, the armature is in a magnetizing field. However, when the armature is in the normal position and the current builds up with a very high rate of rise in the reverse direction, unless proper precautions have been taken in the design, demagnetization can occur. A succession of reverse currents of fault magnitude with high rates of rise in the order of 3 to 4 million amperes per second may completely demagnetize the armature unless some means are employed to prevent the series coil flux from bucking down the armature flux.

1. Trip device characteristic
2. Relay operating time 0.02–0.04 second

In this design, the copper slugs (6, 11) in and around the forward current air gaps are used to prevent demagnetization. The copper slugs oppose a sudden decrease or possible reversal of flux in the pole pieces which they cover. Since these slugs are in two diagonally opposite air gaps, they have no effect on the flux in the other pair of air gaps. The armature has an opportunity to move toward the tripped position without being demagnetized because the sudden reversal of flux is choked in one pair of the air gaps by the copper slugs. Tests made with reverse currents rising at the rate of 3 to 4 million amperes per second up to 13,500 amperes show that the armature is not demagnetized.

For application to generator circuits, the tripping of the circuit breaker must be delayed as described in earlier paragraphs. The time-delay escapement mechanism, 1, 2, and 11 through 14 in Figure 9(A), delays the rotation of the armature as it moves to the tripped position. This escapement is so arranged that it delays the armature only during the first half of its rotation. Thereafter, the armature rotates freely and delivers an impact to release the latch of the circuit-breaker mechanism.

The connection between the escapement mechanism and the armature is a preloaded torsion spring, (1). The action of this spring is best demonstrated by referring to the time-current characteristic curve of Figure 10. If this connection were a rigid member, the time-delay tripping characteristic would be indicated by the dotted line. The series spring, however, yields to the force of the armature at currents of approximately 1,500 amperes and above. A considerable reduction in the tripping time results as shown by the solid curve. This curve indicates the time required by the reverse current trip device to release the latch of the circuit-breaker mechanism at various currents.

Performance Characteristics

The co-ordination between generator relays and one of the new reverse current circuit breakers is shown in Figure 10 by the intersection of the circuit breaker tripping characteristic and the band of opening time of the generator relays. The operating time of most generator relays falls within this band, extending from 0.02 to 0.04 second. Above the intersection of the curve and the band, the circuit breaker trips before the relays open, viding the much-needed backup protection for the relay. This protection is required because of the limited interrupt-ng capacity of the relay.

Below the intersection of the curve and the band, the relay normally opens before the circuit breaker. If, however, the relay fails to open, due to welding of its contacts or improper functioning of the pilot relay, the circuit breaker will open the circuit on reverse currents of 200 amperes or more. The inverse time-current characteristic of the trip device prevents the circuit breaker from tripping falsely on transient reversals. This tripping characteristic is very desirable for generator circuit applications because of the protection which is provided throughout the entire range of currents.

A family of arcing time curves of various altitudes for the 120-volt interrupter is shown in Figure 7. These indicate that over the range of currents up to the interrupting rating and altitude from sea level to 50,000 feet, a maximum arcing time of 32 milliseconds occurs at 600 amperes and 50,000 feet. At lower altitudes and at currents above and below this value, the arcing time is considerably less. The arcing time of the 28-volt interrupter is approximately 1.5 milliseconds and is essentially constant through the entire range of current and altitude. Typical oscillograms of interrupting tests made on 28- and 120-volt circuit breakers are shown in Figure 11.

It is sometimes desirable to know the over-all interrupting time of the circuit breaker to determine the heating effect in other connected devices. This can be obtained at any current by adding the tripping time, the arcing time, and the mechanism operating time. The circuit-breaker mechanism operating time, which is the time from the release of the latch until the contacts start to part, is 5 milliseconds for all values of current. For example, the over-all interrupting time at 5,000 amperes and 50,000-foot altitude for the 120-volt circuit breaker is 24 milliseconds; for the 28-volt circuit breaker at 12,000 amperes and 50,000 feet it is 16 milliseconds.

Auxiliary Contacts

Faults in the generator circuit are isolated from the bus by the opening of the circuit breaker. To stop the flow of power into the fault from the generator, the generator field should be de-energized as the circuit breaker opens. A field switch can be provided in the circuit breaker to do this directly, or the second auxiliary contact, (5) shown in Figure 2(B), can be used to control a relay in the field circuit. The rating of the auxiliary contacts is 10 amperes at 28 volts and 0.3 ampere at 120 volts.

Conclusions

The new aircraft circuit breakers described in this paper meet the requirements of the present-day aircraft electric systems. The continuous current carrying ability and the interrupting capacity of these circuit breakers are adequate for present and proposed 28-volt d-c systems and for proposed 120-volt d-c systems.

Proper co-ordination is obtained between these circuit breakers and generator relays of various types in generator circuits under all conditions. The long time-delay reverse-current trip device developed for these circuit breakers eliminates nuisance trips of circuit breakers in generator circuits. These conclusions are borne out by the results of system tests presented in a conference paper of the

Figure 11. Typical oscillograms of interrupting tests

A. Test at 36 volts, 12,000 amperes and 50,000 foot altitude
B. Test at 144 volts, 5,000 amperes and 50,000 foot altitude

AIEE Pacific General Meeting, San Francisco, Calif., August 23–26, 1949 on A New Aircraft D-C Generator Control System, by Mr. G. A. Phillips.

With instantaneous reverse current and nondirectional trips, these circuit breakers are applicable for bus sectionalizing and in dual- and single-channel feeder circuits and load circuits.

It is believed that the difficulty of obtaining adequate interrupting ability at high altitude has been one of the major problems in the development of 120-volt d-c systems. The development of these circuit breakers and the information now available on interruption performance at altitudes should help further the development of these systems.

An Environment-Free 120-Volt D-C High-Performance Limit Switch

THOMAS R. STUELPNAGEL
ASSOCIATE AIEE

THE *H420A* switch is a newly developed, high performance, hermetically sealed, 120-volt d-c aircraft limit switch. This switch was specifically designed to carry $3^1/_2$ kw and to interrupt a 1.8 kw motor load, 15 times a second, for duty cycles of 15 seconds each.

The development of the *H420A* switch was undertaken because no existing switch would meet these particular requirements and because present 120-volt d-c aircraft electric systems have need for a limit switch capable of interrupting up to 30 amperes of motor current. Electric loads of this nature are now being controlled with switch and sealed-relay combinations which are inherently larger, heavier, and more unreliable than a corresponding switch. This limit switch weighs 1/2 pound and was designed to replace a $2^1/_2$-pound sealed relay.

The purpose of this paper is to discuss, through the medium of a specific design problem, the factors which complicate a seemingly simple device like a 120-volt d-c limit switch, and to emphasize several features of the *H420A* switch that are considered essential though not available in any aircraft limit switch. These features include: positive contact separation in addition to snap action; 8-ounce contact pressures; high-temperature glass-fused mica insulation; a contact assembly capable of interrupting a 1.8 kw motor load one million times without failure; hermetic sealing, and double-break magnetic arc suppression.

Basic objectives in this switch development were first to design a simple long-life mechanism capable of positively opening the switch contacts, and second to obtain environmental-free operation by hermetically sealing the mechanism and contact assembly. Unfortunately, in available aircraft limit switches, the emphasis has been placed on the snap-action contact separation—little effort has been expended in providing positive mechanical follow-up on these snap-action mechanisms which could, in an emergency, open the contacts with the many pounds of force available in the typical operating device instead of the few ounces of force available in the typical snap-action mechanism.

Summary of the H420A Switch Characteristics

Primary considerations in the switch design were a positive break, snap-action mechanism and adequate electrical capacity. Secondary considerations were operating force, differential plunger travel and accuracy of the snap-action trip point. The prototype switch is shown in Figure 1.

Mechanical Features

The switch mechanism incorporates four mechanical features considered essential in an aircraft limit switch.

1. Positive mechanical operation of the contacts as a follow-up to normal snap-action of the switch mechanism.

2. Eight ounces of contact pressure per contact.

3. No detectible contact bounce during switch closure.

4. A magnetic snap-action which maintains substantial contact pressure until after the mechanism trips. In the closed position each contact is mechanically preloaded to 8 ounces by a contact arm deflection of 0.020 inch; therefore, actual contact separation occurs at an interval after the contact armature has been accelerated to a high velocity.

Simplicity

The foregoing mechanical features are obtained without using the complicated lever and spring assemblies common to this type of switch. Such complication is eliminated by using a 1-ounce Alnico V magnet for producing the detent and snap-action. Phenomenal cyclic rate is obtained by combining ample thermal capacity in the contact assembly with magnetic arc suppression. Rapid mechanical operation necessary for such high cyclic rate is secured by applying the operating force directly to the contact armature.

Electrical Capacity

The *H420A* switch is capable of interrupting up to 3.5 kw of 120-volt d-c motor load and was designed specifically to interrupt a 1.8-kw motor load 15 times a second for a 15-second duty cycle. Tests with this switch indicate that the peak voltages resulting from inductive circuit interruption never exceed 1,000 volts be-

Table I

Current carrying capacity	30 amperes
Interrupting capacity (inductive)	30 amperes 120 direct volts (10 operations per minute, L/R of 0.013)
	15 amperes 120 direct volts (900 operations per minute, L/R of 0.003, 15-second duty cycle)
Altitude (hermetically sealed)	100,000 feet
Weight	1/2 pound
Dimensions	1 1/4 × 1 × 3 inches
Plunger force	7 pounds (sea level)
	12 pounds (50,000 feet)
Plunger travel	0.070 inch
Differential travel	0.020 inch
Overtravel	0.100 inch
Mechanical cyclic rate	in excess of 1,000 operations per minute

cause the arc time increases directly with load energy.

Materials

The switch is constructed entirely of metal and a very high quality dielectric composed of fused mica and glass which will stand exceptionally high temperatures and will not track under repeated arcing.

Life

Tests indicate a mechanical and electrical switch life in excess of 50,000 cycles at rated loads.

Hermetic Sealing

Environmental-free electrical operation can be obtained by hermetically sealing the switch at one atmosphere of pressure in dry air. At the design motor load of 15 amperes, 120 direct volts, a hermetic seal is required for operation above 30,000 feet altitude.

H420A Switch Specifications

The specifications for the switch are given in Table I.

Details of the H420A Switch Design

A successful electrical switching operation involves two factors: first, the energy of the electric load, usually inductive, must be thermally absorbed by the switch in the form of arc energy; second, the separation of the switch contacts must introduce enough impedance into the electrical circuit to extinguish this arc after the load energy has been dissipated.

The interrelation of these two factors, coupled with the lack of published data on the variations introduced by different contact materials, rates of contact separation, and atmospheric conditions, makes the job of switch design and switch rating largely experimental.

Test Equipment and Procedures

The test set-up and procedure used in designing the contact arrangement for the *H420A* switch was geared to eliminate much of the time delay and inconvenience associated with the collection of transient switch data. Application of a dual-beam oscilloscope provided simultaneous presentation of switch current and voltage from which measurements of peak voltage, arc current, arc time, and arc energy were readily obtained. A continuous presentation of the switching transient was obtained on the oscilloscope by cycling the test switch at a frequency of 10 to 15 cycles per second. The use of this rapid cycling process for switch investigation is dependent upon the rate of contact temperature rise. However, if a test switch can be rapidly cycled, even in 1-second bursts, a great deal of information can be obtained without the need for a long persistence oscilloscope tube or an oscilloscope camera. The observation of a repeated switching transient insures a typical result and makes the adjustment of synchronization circuits less critical.

Permanent records of switching phenomenon were photographed with a special oscilloscope camera which exposes, develops, and prints each oscillogram in a 1-step 60-second process.

Contact Arrangement

The design of compact, high-capacity 120-volt d-c switchgear is complicated by the fact that the voltage drop across a stable arc remains almost constant with an increase in arc current past 3 amperes, and that this voltage drop even for a one centimeter arc length is less than 40 volts. Theoretical relationships derived by Aytron and Windred[1,2] show that a stable arc is composed of three series voltage drops; an anode drop in the immediate vicinity of the positive contact, a cathode drop at the negative contact, and a column drop between the two. The values of these arc potentials can be calculated from the following equations:[1]

$$\text{Anode drop, } (e_a) = \frac{4a}{5} + \frac{b}{I} \text{ (volts)} \qquad (1)$$

$$\text{Cathode drop, } (e_c) = \frac{a}{5} \text{ (volts)} \qquad (2)$$

$$\text{Column drop, } (e_l) = c + \frac{d}{I} \text{ (volts/centimeter)} \qquad (3)$$

For silver contacts, the values of the constants are $a=19$; $b=11.4$; $c=14.2$; $d=3.6$; I = arc current in amperes.

The theoretical anode voltage drop for a current of three amperes is 19 volts, the cathode drop is 3.8 volts and the column drop is 15.4 volts per centimeter; the total voltage drop across a 1-centimeter arc is, therefore, 38.2 volts. Because of the varying degrees of arc stability which can occur in actual switching operations, it would be difficult to predict the break capacity of a particular switch from the foregoing equations. However, these equations do establish the relative magnitude of each arc characteristic and demonstrate the effectiveness in compact 120-volt d-c switchgear of splitting the arc into a number of series anode and cathode voltage drops with multiple break contacts or deion grids and the ineffectiveness of merely increasing the contact separation.

From the theoretical equations alone, it appears necessary to use four series breaks of 0.1-inch each in a reliable 120-volt d-c switch capable of interrupting the specified 15 amperes. Such an arrangement is impractical, however, because of the mechanical problems involved in supplying adequate contact pressure, operating force, and adjustments to four series contacts in a small snap-action limit switch. In addition to these problems, test results indicated that such a switch would have to be hermetically sealed for reliable, 15-cycle-per-second operation at 50,000 feet.

Magnetic Arc Suppression

The use of magnetic arc suppression, rather than multiple-break contacts, as a means of quenching the arc in a her-

Figure 2. The permanent magnet switch mechanism

metically-sealed 0.1-inch gap snap-action limit switch has several advantages. The increased break capacity and minimum arc energy obtainable with blowout magnets permit the design of a simpler, more compact, 2-break switch capable of interrupting higher energy inductive loads at a given cyclic rate.

Although complete agreement has not been reached in the literature on the theoretical aspects of magnetic blowout, it is generally believed that:[1,3,5]

1. The increased arc path caused by the magnetic field contributes to arc suppression.

2. The rapid movement of the arc across the contact surfaces retards the formation of the molten anode and cathode spots necessary for sustaining an arc.

3. Altitude reduces the effectiveness of magnetic arc suppression until at a critical level the blow out forces have no effect on the arc. At altitudes higher than the critical level, the direction of the arc appears to reverse and the switch break-capacity will then increase.

Were it not for the reduced effectiveness of magnetic arc suppression with altitude, this form of arc quenching would adequately solve the majority of 120-volt d-c switching problems, and in this particular switch there would then be no necessity for hermetic sealing.

Experimentation with the 1/6-ounce blowout magnets used in the subject switch resulted in the location pictured in Figure 1. For the particular conditions of the test (double break contacts with 0.1-inch gaps, silver cadmium-oxide contacts and a 15-ampere aircraft motor load having a buildup time constant of 0.003 second) it was found that the best compromise between altitude and sea level break-capacity could be obtained by supplying a uniform magnetic field between the contacts. Such a field was obtained by locating the blowout magnets in front of the contacts, thereby drawing the arc directly into the magnets. This arrangement affords maximum arc stability, contributes to cooling of the arc gas, and simplifies the magnet mounting problem.

Figure 3. A typical switch testing circuit

The Alnico II magnets used to supply the blowout fields were found to be exceedingly stable when demagnetized to about one half of their maximum flux density. Further tests demonstrated that drawing an arc directly into such blowout magnets had no appreciable effect on their magnetic stability, and that variations of 50 per cent in field strength of the blowout magnets did not measurably alter the switch break-capacity. During life tests 2,000,000 15-ampere 1.5-joule arcs were drawn into the blowout magnets at a continuous rate of 15 cycles per second without affecting their field strength. The emergency overload capacity of the switch was demonstrated in a second test when 75-ampere 70-joule arcs were interrupted 10 times a second for 100 1-second duty cycles without altering the blowout field.

Contact Materials

The selection of suitable contact materials was found to be of fundamental importance in the design of a high cyclic rate, high-capacity switch. Preliminary tests indicated that arc energy, and consequently the contact temperature and life were intimately associated with the contact material used. In addition the high contact temperatures encountered even with materials demonstrating low arc energy required that the contact be riveted rather than brazed or resistance welded to the contact arm.

A silver cadmium-oxide contact material was found to give the best results of several materials tested because it exhibited superior qualities of low arc energy, long life, and high electrical conductivity; and is ductile enough to be riveted directly to the contact arm. As a result the contacts can be overloaded to a red heat without apparent damage.

The importance of selecting suitable contact materials was demonstrated by life tests conducted with the circuit shown in Figure 3. In these tests a 15-ampere simulated motor load was interrupted continuously 15 times a second with a double-break magnetic blowout switch; the switch contacts were not externally cooled. Two life tests were conducted with $^1/_4$-inch diameter silver-cadmium-oxide contacts riveted to beryllium copper arms. Each set of these contacts went 1,000,000 consecutive cycles without failure and a maximum contact temperature of 400 degrees Fahrenheit resulted from the 1.5-joule arc energy.

When the identical test was attempted with silver tungsten-carbide contacts, brazed to similar contact arms, failure occurred after 4,500 cycles of operation because tripled arc energies resulted which in turn caused contact temperatures in excess of 1,000 degrees Fahrenheit. The high temperature caused these contacts to erode rapidly and eventually fall off.

Transient thermal capacity was provided in the *H420A* switch by riveting the stationary silver-cadmium-oxide contacts to solid copper blocks having 20 times the mass of each contact.

Switch Mechanism

The permanent-magnet detent mechanism provides the essential limit switch features of adequate contact pressures, snap-action "make" and "break", no detectible contact bounce and a positive mechanical contact separation. In addition, the mechanism is rugged, simple, and extremely rapid.

Operation of this mechanism, shown in Figure 2, results from the difference in shape of the force-distance curves of a magnet and a spring. During the plunger pretravel the plunger spring is compressed against the contact armature which in turn is held against the detent magnet with ten pounds of magnetic pull. When the plunger spring is compressed to a force sufficient to overcome the difference force between the detent magnet and the contact preload, the armature is suddenly released by the magnet and driven to the full open position by the energy stored in the spring. During opening, the armature driving force is the difference force between the opposing spring and magnet. A mechanical opening speed of about 2 milliseconds results because this force of more than a pound is applied directly to the contact armature. If, after the switch has been opened, the plunger position is reduced 0.020 inch from the trip point, the slope of the magnetic force curve becomes greater than that of the spring curve and the armature snaps shut.

Should gross electrical overloads weld the contacts, the switch overtravel causes the plunger to bottom directly on the contact armature. Extensions of the contact armature, not shown in Figure 1, then open the contacts with a force transmitted directly from the operating device.

Eight-ounce contact pressure is provided in the *H420A* switch. In view of the vibration, contact bounce, and surface oxidation problems encountered with switches and relays having contact pressures less than 4 ounces, it appears very desirable on a series break device using silver base semirefractory contact materials to have 8 ounces of contact pressure per contact.

Figure 4. Altitude characteristics of an unsealed double-break magnetic blowout switch. The electrical circuit constants are given in Figure 3

Contact gap: 0.1 inch, contact material: silver cadmium-oxide

Substantial contact pressure is maintained until after the switch mechanism trips. With the perfect magnetic detent device, constant contact pressure would be maintained until the contact armature was suddenly snapped open. In the actual device, mechanical tolerances contribute to a reduction of contact pressure from 8 ounces to 6 ounces as the plunger trippoint is approached.

Contact bounce during switch closure has been minimized by combining the magnetic snap-action mechanism with a low inertia spring loaded contact assembly. Minimum contact bounce is especially important when such a switch is used for d-c motor control because motor surge currents several times greater than the running current build up in a few milliseconds after contact closure.

Hermetic sealing in a high permeability case increases the reliability of the permanent magnet mechanism by excluding foreign matter and effectively shielding the detent magnet from external fields.

Hermetic Seal

The reduced effectiveness of magnetic arc suppression with altitude requires that the *H420A* switch, when interrupting the specified 15-ampere motor load, be hermetically sealed for reliable operation above 30,000 feet.

Some of the more obvious problems involved in such an hermetic seal are:

1. Transmission of mechanical movement and electrical energy through the seal.
2. Selection of proper sealing atmosphere.
3. Effect of altitude and temperature on switch operation force.
4. Prevention of excessive temperature rises near the soldered joints of the case.

The hermetic seal has not yet been tested; however, a brief discussion of this seal has been provided for completeness of the switch report. Glass to metal terminals capable of handling 30 amperes were selected for the electric connections. A bellows rather than a diaphragm has been used for transmission of mechanical movement because of the large travel obtainable (0.3 inch maximum in the specified bellows), ruggedness, reproducibility and a life expectancy in excess of 50,000 operations. The switch case is 1/32-inch steel, silver soldered at all joints except the top and electrical terminals. The sealing atmosphere is dry air.

Insulation

There is no easy solution to the problem of insulating an electrical arc. Unfortunately, the insulators that can withstand the intermittent arc temperatures of several thousand degrees without breaking down or carbon tracking are of a ceramic nature. Ceramics meeting the requirements were brittle, difficult to machine and expensive to assemble.

If these mechanical problems associated with the use of ceramics are accepted as the price to pay for excellent arc insulation the rewards are gratifying. All of the insulation in the *H420A* switch is glass-bonded mica, a material which has excellent high temperature characteristics, will not carbon track, is reasonably machinable, and can be bonded to itself or metal with a special high-temperature ceramic cement. For arc insulation, this material proved far superior to glass-silicone laminates, melamine or Bakelite.

The insulation problem of a low production switch, where quality rather than cost is the controlling factor, can be effectively solved by surrounding the switch mechanism with 1/16-inch thick pieces of glass-bonded mica which are mechanically interlocked and then bonded to the metal switch case with the ceramic cement.

Figure 5. Break-capacity of a hermetically sealed *H420A* 120-volt d-c aircraft limit switch

These curves were obtained with an unsealed switch operating at sea level pressure and 10 cycles per second for 1-second intervals. Inductance ratings are based on current rise time

Figure 6. Typical oscillogram of the *H420A* switch interrupting a 15-ampere inductive load. Electrical load L/R ratio = 0.012

The switch shown in Figure 1 contains insulation of this type.

Altitude Characteristics of an Unsealed Switch

The break-capacity of an unsealed *H420A* switch at altitudes up to 60,000 feet has been presented in Figure 4. The break capacity of the unsealed switch when interrupting the simulated motor load described in Figure 3 is 58 amperes at sea level, linearily reduces to 22 amperes at 40,000 feet, and then suddenly drops to 6 amperes at 45,000 feet. Arc reversal phenomenon was observed at altitudes.

Break capacity was based on maintaining a constant 10-milliseconds arc time. Further testing and data reported in the literature indicate that the altitude at which the blowout forces disappear or in some instances reverse in direction, depends upon the variables of switch gap, contact materials, contact temperature, blowout field strength and location, load current, and possibly the speed of contact separation. Because of the large number of variables involved in a particular switching operation the altitude characteristics shown in Figure 4 cannot necessarily be extrapolated to higher inductive loads.

Switch Break Capacity

Hermetically sealed at one atmosphere of pressure, this switch has an unusually high 120-volt d-c break capacity. The magnetic blowouts suppress the arc as soon as the stored load energy has been dissipated and in addition the magnetic field drives much of the arc thermal energy away from the contacts themselves. The data presented in Figure 5 shows the switch arc time which results from the interruption of various inductive loads having current rise inductance-resistance ratios up to 0.025. Four low-loss iron core inductors, with an inductance range of 10-to-1, were used to obtain these curves. The switch was cycled in 1-second bursts at 10 cycles per second.

For all practical purposes the switch arc time was found to have a constant value for a given circuit time constant or inductance-resistance ratio. For example: the interruption of inductive loads having a current rise inductance-resistance ratio of 10 milliseconds resulted in an arc time of 5 milliseconds; the interruption of a 20-millisecond inductance-resistance ratio resulted in a 11 milliseconds arc time. This characteristic provides a convenient basis for rating the *H420A* switch.

Peak voltages resulting from interruption of the inductive loads described in Figure 5 never exceed 1,000 volts. This characteristic is of particular importance because it is not unusual for d-c aircraft switches to cause peak voltages over 5,000 volts.[4] In most instances the peak voltages measured across the *H420A* switch decreased with an increase in arc time past 3 milliseconds. An arc modulation frequency of several kilocycles was observed in arcs lasting longer than 5 milliseconds. A typical oscillogram of the transient switch current and voltage resulting from the interruption of a 15-ampere inductive load has been reproduced in Figure 6.

No Discussion

The Design of Reactors for Radio Interference Filters

L. I. KNUDSON
NONMEMBER AIEE

RADIO noise filters in their simplest form may consist of a capacitor inserted between the interference source and that portion of the circuit that is to be isolated. The attenuation of such a filter is limited by the inherent impedance of the leads between the noise generator and the capacitor. It is economical to provide additional impedance at this point in the form of a reactor. Figures 1(A) and 1(B) show the two conditions.

The load or output voltage E_0 neglecting Z_g and taking Z_L as the impedance of the capacitor in parallel with the load is evidently given by

$$E_0 = \left(\frac{Z_L}{Z_S + Z_L}\right) E_g \tag{1}$$

and in general, it is desirable from an attenuation standpoint to have Z_g as large as possible and Z_L as small as possible. Resonant conditions which eventually occur as the frequency is increased are a serious limitation on a single section filter. Additional high-frequency sections may be added to provide attenuation where the above section becomes ineffective. The problem of particular interest in this paper, however, is the consideration that may be given to the reactor.

Closer inspection of Z_s reveals that Figure 2 is representative of an equivalent circuit for an inductor containing a high-loss magnetic material where L_x is the inductance, R_x is the shunting effect due to iron losses, R_w is the actual winding resistance taking into account the skin effect, and C_d is the distributed capacity. The distributed capacitance may have losses, but these are generally swamped by those already stated. For direct current and low-frequency alternating currents R_x becomes very high while R_w approaches the d-c value of the winding. From a radio-interference-filter standpoint and the expression of equation 1, R_x, L_x, and R_w may be large, while C_d should be as small as possible so that antiresonance of L_x and C_d may occur at as high a frequency as possible. Low values of R_x are desirable as a means of preventing unwanted drop in power currents which also is true of L_x for alternating currents. The desirability of high L_x and R_w for attenuation against radio-influence currents as against low L_x and R_w for low attenuation against power currents is a designer's compromise.

A factor occasionally overlooked is that relatively low values of R_x may be tolerated in radio-interference filters, as the filter operates well beyond cut off where rapid transition from pass to stop is not generally required. Consider that R_x is primarily responsible for limiting the Q factor of the coil. Figure 3(A) is the circuit and Figure 3(B) is a plot of the absolute value of normalized impedance versus Q, where Q is taken as $R_x/\omega L_x$. Note that values of Q as low as three reduce the impedance to only 0.707 of the unloaded value.

As the reactor is examined at increasingly greater frequencies, it will be observed that R_x reduces, as the iron losses will increase with frequency and reactance of the distributed capacity becomes appreciably low. R_w of Figure 2 may generally be neglected so that Figure 4 is the equivalent circuit.

Equation 2 expresses the impedance of this circuit but R_x should be considered as being a complex function of frequency.

$$Z_s = \frac{\dfrac{1}{R_x} - j\left(\omega C_d - \dfrac{1}{\omega L_x}\right)}{\left(\dfrac{1}{R_x}\right)^2 + \left(\omega C_d - \dfrac{1}{\omega L_x}\right)^2} \tag{2}$$

At the natural frequency of the coil the impedance becomes simply R_x which may or may not be a high value. For frequencies greater than the natural frequency, Z_s becomes less and less. It is well to reduce C_d as much as possible and this may be done by obtaining the inductance by connecting in series a multiplicity of coils the antiresonant or natural frequency of any one coil being the limiting factor. π windings and even straight solenoidal windings are examples of such arrangements. Space-wound solenoids are still more effective in this respect and should the spacing be increased without limit a straight wire results. The anti-

Figure 2. Equivalent circuit of inductor

resonant frequency for the straight wire occurs when it becomes electrically a half wave length long.

Suitable coils may take many forms. Figure 5(A) represents one arrangement whose greatest merit is ease of manufacture. Figure 5(B) represents an improvement over Figure 5(A) as a return flux path is provided. Figure 5(C) is quite similar except that somewhat higher distributed capacity may offset the increased inductance value.

Figure 6 is still better and makes good use of available space, allows a very close fitting shield to be used, and has a relatively low value of distributed capacity.

The saturation effects of load currents should be checked although the large airgap provided by Figure 5(A) plus the intrinsic airgap of powdered iron due to the interstices between the iron particles generally prevents saturation. Figure 6, however, should be carefully checked as saturation may easily occur. This becomes particularly so should end caps of magnetic material be added forming a familiar cup core.

The foregoing remarks are doubly applicable to the toroid and variations of the toroid. The toroid provides a satisfactory filter reactor as the external magnetic flux is almost nil, the distributed capacity may be satisfactorily low and for a given space requirement provides a good value of inductance. As only single-layer windings generally prove practical the difficulty of winding such a coil is considerably relieved. The toroid may utilize 0.001–0.003 inch laminations of ferrous material as parallel rings or as a continuous wound strip. Alternatively the core may be molded from the ferrites or from the more conventional powdered irons. All such cores require an airgap whose value may be for the ferrous and ferrite materials computed from the method of Hanna,[4] while for the powdered irons an intrinsic airgap is effected by the interstices between the iron particles. In both cases it is the incremental inductance that is of interest as the load currents are much greater than the radio-influence currents.

Computations on closed toroids of rectangular cross section which may or may not have an intrinsic airgap may be made rather easily from the following relations. The total F is given by

$$F=\frac{4\pi NI}{10} \quad \text{gilberts} \tag{3}$$

$$H=\frac{4\pi NI}{2\times 10\pi r}=\frac{2NI}{10r} \quad \text{oersteds} \tag{4}$$

$$B_\Delta=\frac{2NI}{10r}\mu_\Delta \quad \text{gausses} \tag{5}$$

where μ_Δ is a function of H for saturable materials.

$I=I_0+I_\Delta$

b = core width

R_2 = outer radius

R_1 = inner radius

and as by definition

$$L_\Delta=\frac{N\phi_\Delta}{I_\Delta}\times 10^{-8} \text{ henrys} \tag{6}$$

together with equation 5 gives

$$L_\Delta=\frac{2N^2b}{10}\int_{R_1}^{R_2}\mu_\Delta\frac{dr}{r}\times 10^{-8} \quad \text{henrys} \tag{7A}$$

The μ_Δ may be held constant to an average value of $1/2\ (\mu_{\Delta_2}+\mu_{\Delta_1})$ as an approximation whose error becomes nil as $R_2-R_1\rightarrow 0$.

Values of μ^Δ are taken from curves relating μ_Δ versus H. Where R_2-R_1 is appreciable the integration may be done

Figure 4. Equivalent circuit of inductor neglecting series resistance only

in parts using different values of average μ_Δ. Equation 7(B) expresses this relation and in addition is applicable to the simultaneous use of different core materials arranged in annular fashion where μ_Δ under a particular integral may be taken as an average value between the limits of integration or as an exact value taken as a complex function of r from the μ_Δ versus H curves.[1]

$$L=\frac{2N^2b}{10}\left[\int_{R_1}^{R_2}\frac{\mu_{\Delta_2}dr}{r}+\int_{R_2}^{R_3}\frac{\mu_{\Delta_3}dr}{r}\times\int_{R_{\mu-1}}^{R_\mu}\mu_\Delta dr\right]\times 10^{-8}H \tag{7B}$$

For toroids with round cross sections, equation 8 of reference 2 is included where r_1 is radius of core section.

$$L=\frac{4\pi N^2}{10}\left[R-\sqrt{R^2-r_1^2}\right]\mu_\Delta\times 10^{-8}H \tag{8}$$

Equations 7 and 8 may be written as

$$L=N^2\rho \tag{9}$$

where ρ is the permeance of the magnetic circuit. In general, when the turns occupy substantially the same space in any coil ρ remains constant except for saturation effects.

This equation may be plotted and the parallel lines with a slope of two of Figure 7(A) are loci for different values of ρ. Figure 7(B) is a plot on log–log paper of ampere turns versus ρ for a given toroid. Use of Figures 7(A) and (B) allows rapid calculation of incremental inductance for various values of d-c load current. The bending to the right of the ampere turns versus ρ curve is due to saturation while the extreme left vertical line is the curve

Figure 9. High-frequency inductor with composite core

for an air-core toroid. The μ_Δ for identical size cores is given by the ratio of the permeance for an iron core to the permeance of an air core.

Figures 7(A) and (B) provides rapid determination of the inductance for a coil with a given number of turns and d-c load current. Figures 7(A) and (B) are most applicable for evaluating existent cores operating under various conditions. Intersection of the ampere turns versus ρ curves indicates that point at which one core becomes more suitable than another. Figure 8(A) is a B versus H curve and Figure 8(B) is a μ_Δ versus H curve for five different magnetic materials. The crossing points on these curves indicate where one material provides greater μ_Δ than another for a given magnetizing force.

One type of toroid which is of particular interest for construction of high-current filters passing several hundreds of amperes and/or for high-frequency sections, consists of a straight round conductor surrounded by a suitable annular core. It will be shown that this is very nearly equivalent to a single turn toroid and for practical purposes the same formulas are used except that N^2 becomes unity. The package-ability, low d-c drop and high antiresonant frequency combine to affect a low value of inductance. Equation 7(B) is directly applicable to the arrangement of Figure 8(B), where several different magnetic materials are arranged annularly.

In argument for the foregoing statements, consider a long, straight, round very small diameter wire carrying current I. The magnetic intensity at a point p external to the wire is given by equation 10 of reference 3

$$H=\frac{I}{10r}(\cos\alpha_1+\cos\alpha_2)\text{ oersteds} \tag{10}$$

In equation 10 and Figure 10, H is in oersteds, I is in amperes, and r is in centimeters. Should point p be symmetrically located so that $\alpha_1=\alpha_2=\alpha$ and the wire length is large compared to r the expression reduces to

$$H=\frac{2I}{10R} \tag{11}$$

From Figure 10(B) the total flux is given by

$$\phi=b\int_{R_1}^{R_2}\frac{2I}{10r}dr\mu_\Delta \tag{12}$$

provided μ_Δ is sufficiently large to render that flux between wire center and R_1 and R_2 and $R_=$ insignificant which is generally the case. The inductance by definition being:

$$L=\frac{N\phi}{I}\times10^{-8}$$

becomes for this case of $N=1$

$$L=\int_{R_1}^{R_2}\frac{2I}{10r}dr\mu_\Delta\times10^{-8}\text{ henrys} \tag{13}$$

Additional terms may be added if required so that equation 7(B) will result. Should μ_Δ be constant for the magnetic intensity varying from R_1 and R_2, equation 13 reduces to

$$L=\frac{b2I}{10}\mu_\Delta\ \ln\frac{R_2}{R_1}\times10^{-8}\text{ henrys} \tag{14}$$

Dividing equations 13 and 14 by b gives inductance per unit length for a long wire but in actual practice where μ_Δ is substantial the equation holds quite well for finite values of b.

Another point to emphasize is that the magnetic intensity at a point P is independent of conductor size provided P is external from the concentric conductor. This follows by recalling that the total F acting around the conductor may be computed as the line integral of magnetic intensity through P Figure 10(A). The integration taken over a concentric circle through P gives from equation 11

$$F=\frac{2\pi r2I}{10r}=\frac{4\pi I}{10}\text{ gilberts} \tag{15}$$

which is the total magnetomotive force. Note that the radius has dropped out indicating that any path of integration in a

Figure 10(A) (below). Conductor carrying current I producing magnetic intensity at point P as given by equation 10

Figure 10(B) (below). Section of conductor carrying current I surrounded by annular magnetic material with inner radius R_1 and outer radius R_2 used to derive equation 12

Figure 11 (right). Curve providing relations between current for single conductor, ampere turns for multiple conductors, radius to a point, and field intensity at that point

panel perpendicular to the wire could have been followed. Although Figures 10(A) and (B) together with equations 11, 12, 13, and 14 were postulated around a thin round conductor, from equation 15 it follows therefore that any conductor of symmetrical shape will produce an F equal to $0.4\,\pi\,I$.

As magnetic intensity is F per unit length, one may divide by the flux path length $2\pi R$ and arrive again to equation 11. As the magnetic force at that point is independent of conductor size and mediums between the conductor and point provided the medium does not conduct electrically or dielectrically due to very high dielectric constant, but does depend on distance r from conductor axis and on current, the plot of Figure 11 showing H versus r for values of current is useful. This curve provides rapid determination of magnetic intensity for a given coil and allows one to check the degree of saturation that may exist from the μ_Δ versus H curves. It should be apparent that the diagonal lines are in reality ampere turns and may be used to rapidly determine the magnetic force at a point in a toroid as well.

An example of a composite design is given by first stating the problem. Determine the optimum unit inductance of a conductor carrying intermittently 100 amperes of direct current. Outside diameter of conductor $=0.4$ centimeter, maximum coil diameter 1.4 centimeters, the coil radius varies from 0.2 to 0.7 centimeter which is a variation from Figure 11 of 100–28 oersteds. Figure 8(B) indicates that the curves for material A and C intersect at 75 oersteds which from Figure 11 corresponds to a radius of 0.26 centimeter. From radius of 0.2 to 0.26 centimeter, material A is used. From 0.26 to 0.7 centimeter, material C is used. The inductance per-unit length is determined from equation 7(A). Using average values of $\mu_{\Delta A}=25.75$ and $\mu_{\Delta c}=61.25$ and $N=1$ and $b=1$ centimeter for materials A and C respectively integrating equation 7(B) gives

$$L_\Delta=2\left[\mu_{\Delta A}\ln\frac{r_a}{r}+\mu_{\Delta c}\ln\frac{r_c}{r_a}\right]10^{-9}$$

$$=0.135\,\mu H/\text{cm}$$

In another case a high-frequency section is desirable. About 7 amperes of direct current is carried continuously, indicating that number 16 wire would be suitable. Allowing a hole of 0.080-inch diameter for this wire and a maximum diameter of 0.375 inch, what is the best material and what is the unit inductance? Figure 11 shows that for a radius of $0.04 \times 2.54=0.102$ centimeter a magnetic intensity of 13.5 oersteds will exist. The greatest average permeability taken between the outside diameter and inside diameter specified above, from Figure 8 (B) is 87.25, and is given by material E. Again from equation 7(B) the inductance becomes

$$L_\Delta=2\mu_\Delta\ln\frac{r_3}{r_2}\,10^{-9}\text{ henrys}$$

$$=0.27\mu H/\text{cm}$$

Conclusions

Interesting possibilities of inductor designs have been presented together with typical graphical information for various available materials. It is shown to a reasonable approximation that for a straight conductor or a toroid that the magnetic intensity is inversely proportional to the radius. Of particular interest is the use of composite materials for use in both toroids and straight-wire inductors. The latter group are of particular importance due to the high antiresonant frequency. This allows construction of efficient and effective high-frequency sections.

Series-Connected Saturable Reactor with Control Source of Comparatively High Impedance

H. F. STORM
MEMBER AIEE

Synopsis: The object of this analysis is to form a clear picture of the function of the saturable reactor with resistive load, and to derive simple, and yet reasonably accurate equations. Four modes of operation are analyzed for normal and underexcitation and one mode of operation for overexcitation. The results of the mathematical derivations are condensed into graphs in normalized form. With the aid of these graphs the effect of any circuit parameter can be readily understood. A numerical example is included to demonstrate the usefulness of the normalized graphs for the quick calculation of the saturable reactor.

SATURABLE reactors may be classified as series-connected or parallel-connected, depending upon the respective connection of the load windings. The function of the saturable reactor is further determined by the relative magnitude of currents induced into the control windings from the load windings. These induced currents become larger as the outer control-circuit impedance decreases and therefore are largest when the outer control-circuit impedance is zero; conversely, for very high outer circuit impedance the induced currents become practically zero. Consequently, each class of saturable reactor may be subdivided into one category where the outer control-circuit impedance is comparatively small and another where the outer control-circuit impedance is relatively high. In order to accentuate the differences between these two categories, one may assume extremes for the outer control circuit impedance; namely, zero for the first category and infinity for the second. In the following pages only the latter category will be analyzed. Reactors approaching this case have many applications, including the measurement of large direct currents[1] and the production of constant direct currents and voltages.

A rigorous analysis of saturable reactor circuits become quite difficult due to the presence of nonlinear and multivalued functions. The following analysis relinquishes some rigor in return for a quicker and clearer understanding of the fundamentals of reactor circuits. In addition, it permits one to calculate performance simply and yet with a reasonable degree of accuracy. To this end, simplifications are made in such a manner as to obtain good agreement of theoretical calculations and actual results. It should be kept in mind, however, that simplifications, by their very nature, result in derived solutions which are accurate only as long as the simplifications closely approximate actual conditions. This reservation should be remembered when interpreting the results of this paper.

One approximation consists in reducing the hysteresis loop to a single-valued function; this is permissible because core losses are not considered in this analysis. The wide present-day use of grain-oriented steels and other square-loop materials permits a further simplification of the magnetization line. Because such materials are characterized by a high differential permeability (over 50,000 gauss per oersted) and a sharp knee of the B-H curve, the latter is assumed of rectangular form, see Figure 1. Leakage reactance of the load windings is considered negligible in comparison with the load resistance, and the resistance of the load windings is lumped with the load resistance R_L. Operation is considered for steady state only.

The saturable reactor described in the following consists of two magnetic circuits, Figure 2, arranged in such a manner that they cancel voltages of fundamental frequency and odd harmonics in the control circuit.[2] The two magnetic circuits may consist of two separate units A and B as shown, or they may be embodied in a 3- or 4-legged construction, without change of basic performance. Each of the two units exhibits the essentials of a single-phase transformer: an iron core, one winding $X1$-$X2$ connected as a load winding, the other winding $Y1$-$Y2$ used as a control winding. The load resistance R_L is connected in series with the two load windings ($X1$-$X2$) and a rectifier instru-

Figure 4 (above). Permanent magnet current standard, maximum burden 10 watts

ment, reading the average value I_L of the rectified load current. Increasing the control voltage E_C will strengthen the control current I_C and result in a larger load current I_L. As will be shown later, control current and load current are proportional over a wide range; hence this circuit can be used for measurement purposes. This proportionality is obtained despite variations of line voltage, frequency, and load resistance (burden).

The dots in Figure 2 signify winding polarities. A current is called positive when it flows through the winding in a direction away from the dot. The magnetomotive force is called positive when derived from a positive current and the positive direction is indicated by the arrows near F_A and F_B. A voltage across a winding is defined positive when the terminal with the dot is more positive than the other terminal. A-c supply voltage e is counted positive when the a-c bus with the dot is the more positive one.

Figure 3. D-c transformer 3,000/5 amperes, approximate weight 50 pounds

Our premise of negligible, induced currents in the control windings is schematically indicated in Figure 2 by the insertion of an inductance L_C; a resistance or a combination of resistance and inductance would serve as well. This condition of negligible, induced currents occurs naturally in d-c meter transformers for large currents, such as the 3,000-ampere model shown in Figure 3, where the control winding consists simply of the d-c bus whose current is to be measured.

The condition of no induced control currents also occurs in the permanent magnet current standard, Figure 4, where the d-c magnetomotive force is obtained from a permanent magnet. The effect of the permanent magnet is in the circuit shown in Figure 5 is similar to a constant control current in the circuit of Figure 2. Remembering that load current and control current are proportional, it follows that with a permanent magnet, the load current will remain constant. This constancy holds despite considerable variations in line voltage, frequency, and burden.

The Normal- and Underexcited Saturable Reactor

Zero Load Resistance

In order to win a toehold on the problem, let us assume that the load resistor R_L in Figure 2 has been shorted by switch *S2*, while switch *S1* was still open. The control voltage source E_C drives the control current I_C through the two control windings. As with other a-c circuits containing resistance and inductance, a switching transient should be expected when switch *S1* is closed at a random time. However, if the switch is closed at the instant at which the steady-state value of the alternating current would be zero, no switching transient will result.[8] In linear, purely inductive circuits the alternating current becomes zero when the voltage reaches its crest value and it suggests itself to close switch *S1* in our nonlinear circuit also at this instant ($\theta = \pi/2$, Figure 6)

Let

$$\theta = \omega t \tag{1}$$

and the supply voltage

$$e = E_m \sin \omega t \tag{2}$$

Before closing switch *S1*, the magneto-

Figure 6. Wave shapes in various parts of the circuit of Figure 2, for load resistance $R_L=0$

motive forces in the cores are due to the control ampere-turns only. The resultant flux is obtained from the magnetization lines of the cores shown again in Figure 6(I) for core A and in Figure 6(J) for core B. For $\theta<\pi/2$ the magnetomotive forces are 0 to 1′ and 0 to 7′, and the core fluxes are 1 to 1′ and 7 to 7′. The operating points 1 and 7 are located on the saturation branches of the magnetization lines and hence the fluxes ϕ_A and ϕ_B equal the saturation flux Φ_s. If the magnetomotive force in the core is changed, for instance, by a current flowing in the load winding, such current will not cause a change in the fluxes ϕ_A or ϕ_B when the load current is positive, nor will it produce a change of flux when the load current is negative, qualifying the latter case for load ampere-turns not exceeding control ampere-turns. This means that the flux linkages remain constant and therefore no inductance will be exhibited by the reactor for the circumstances just mentioned.

Suppose switch $S1$ is closed at $\theta=\pi/2$, impressing a voltage e, Figure 6(B), on the circuit which at this moment has no inductance and which according to a previous assumption has no resistance. Under the effect of the line voltage e the load current will rise with a vertical front, Figure 6(C). The directions of the load current i_L and the driving voltage e are the same. Because of the polarities observed.

$$i_{L,A}=i_L \tag{3}$$

$$i_{L,B}=-i_L \tag{4}$$

The load ampere-turns are positive in core A and negative in core B. As previously pointed out, a positive increase

Figure 7 (left). Wave shape of load voltage $I_L R_L$ for mode 1 operation

Figure 8 (right). Oscillogram of supply voltage e and load voltage $I_L R_L$ for mode 1 operation

of ampere-turns in core A will produce no inductance in unit A, and will produce no inductance in unit B until

$$-i_{L,B}N_L = I_C N_C \tag{5}$$

Thus the load current will rise with a vertical front to

$$i_L = -i_{L,B} = I_C N_C / N_L \tag{6}$$

The points reached on the magnetization lines are denoted by *2* for core A, Figure 6(I), and *8* for the core B, Figure 6(J). At this instant, which is designated by $\theta = \pi/2 + 0$, the steep region 12 to 8 in core B is reached and thence unit B will exhibit an inductance L. The current i_L follows from

$$e = L\frac{di_L}{dt} = \omega L \frac{di_L}{d\theta} \tag{7}$$

and

$$i_L = \frac{1}{\omega L}\int_{\pi/2}^{\theta} e \, d\theta + C \tag{8}$$

At the starting instant $\theta = \pi/2$ the integral of equation 8 is zero and hence

$$C = I_L \tag{9}$$

Substituting from equations 2 and 9 into equation 8

$$i_L = I_L\left[1 + \frac{E_m \pi}{\omega L I_L}\sin\left(\theta - \frac{\pi}{2}\right)\right] \tag{10}$$

where

$$\pi/2 < \theta < 3\pi/2$$

It follows that the load current consists of a constant component I_L on which a sinusoid is superposed. In practical cases $E_m/\omega L I_L$ is a small quantity because the high permeability in the core produces a large L. The term I_L of the load current is proportional to the control current I_C equation (6).

For $\pi/2 < \theta < \pi$ electric energy is received from the line and is returned to the line over an interval of equal length. Therefore at $\theta = 3\pi/2$ all energy has been returned and current i_L can no longer be maintained against the opposing line voltage e. The current collapses at $\theta = 3\pi/2$ and then assumes the same direction as the instantaneous line voltage. The current now flows in its new direction for π radians until it again reverses. The result is a square wave shown in Figure 6(C).

It is also important to note that a variation in supply voltage E_m and frequency $f = \omega/2\pi$ affects only the term $E_m/\omega L I_L$. Any variation of this term which is small in itself, will produce only a minor variation of i_L. From these observations one draws the important conclusion that the load current i_L is proportional to the control current, and that line voltage or line frequency variations have only a minor effect. Thus the circuit shown in Figure 2 can be used to measure current. This technique becomes particularly practical for large direct currents, where cost, space, and power loss in shunts become an appreciable item. It should further be observed that rectification of the square wave load current produces a nearly perfect direct current. Because an instantaneous change in control current produces a proportional, instantaneous change in load current, the rectified load current becomes a replica of the control current, scaled down by the turn ratio N_C/N_L. The circuit therefore exhibits the properties of a d-c transformer.

By replacing the control ampere-turns by a permanent magnet, Figure 5, the circuit now produces a current which is nearly independent of line voltage and frequency. Such a device is used as a voltage or current standard. It should be mentioned that in cases where practically complete independence from line voltage and frequency variations is required, a simple compensating circuit is added.

Summarizing, one may state that for the theoretical case of a perfectly rectangular magnetization line $L = \infty$, and the load current is a square wave whose height is so controlled by the control current I_C that the control ampere-turns equal the load ampere turns (equation (6). Line-voltage and line-frequency variations have no effect on the magnitude of the load current for normal and underexcitation as defined later.

Because of the saturation of core A during $\pi/2 < \theta < 3\pi/2$, no voltage appears across the terminals of unit A, (Figure 6 (D). However, during the same interval core B is unsaturated and therefore capable of balancing the line voltage across its terminals *X1-X2*.

Because of the polarities involved the coil voltage

$$e_{L,B} = -e \tag{11}$$

This is shown in Figure 6(E). Since no saturation is present, voltage $e_{L,B}$ will be transformed fully to the control winding according to

$$\frac{e_{L,B}}{e_{C,B}} = \frac{N_L}{N_C} \tag{12}$$

The voltage induced in the control circuit (*Y1* of A to *Y2* of B) is illustrated in Figure 6(F). As a result of the voltages $e_{L,A}$ and $e_{L,B}$, the core fluxes ϕ_A and ϕ_B will change. For instance

$$\frac{d\phi_B}{dt} N_L 10^{-8} = e_{L,B} \tag{13}$$

Substituting from equations 1, 2, 11, and 13 one obtains

$$\phi_B = \Phi_s + \frac{E_m}{\omega N_L} 10^8 \cos\theta \tag{14}$$

This flux consists of a constant component Φ_s, the saturation flux, and a superposed flux swing ϕ_Δ

$$\phi_\Delta = \Phi_{\Delta,m} \cos\theta \tag{15}$$

where the maximum flux swing

$$\Phi_{\Delta,m} = \frac{E_m}{\omega N_L} 10^8 \tag{16}$$

Finally one obtains from equations 14 15, 16

$$\phi_B = \Phi_s - \Phi_{\Delta,m} \sin\left(\theta - \frac{\pi}{2}\right) \tag{17}$$

For $\pi/2 < \theta < 3\pi/2$ the core flux undergoes a sinusoidal swing as shown in Figure 6 (H). For the other half-cycle an analogous flux swing occurs in core A, Figure 6(G). It should be noted also that the flux swing does not depend on the inductance L of the load winding (equation 16). It also is apparent that if the flux swing should exceed twice the saturation flux Φ_s, core B would become newly saturated along branch 12 to 14, and hence unit B will lose its inductance. When this happens a different mode of operation results. It therefore becomes necessary to further subdivide the reactor operation;

the reactor will be called normal excited when the maximum flux swing, $\Phi_{\Delta,m}=2\Phi_s$, overexcited when $\Phi_{m\Delta,}>2\Phi_s$, and underexcited when $\Phi_{\Delta,m}<2\Phi_s$. All previous equations hold only for normal or underexcited reactors.

Next, let us investigate the effect of changing the polarity of the control voltage. The control ampere-turns then become 0–6′, Figure 6(I), and 0–13′ Figure 6(J), and the flux positions become 6 and 13, respectively. If again for $\theta=\pi/2+0$ switch *S1* of Figure 2 is closed, the load current will increase exactly as previously explained and also will follow exactly the same pattern as for a positive E_C. In other words, the load current cannot discern the polarity of the control source. For $\theta=\pi/2+0$ points 5 and 14 are reached on the magnetization line, and the supply voltage e is now balanced by the flux change in core A, while core B becomes saturated. The voltage across terminals *Y1* of unit A to *Y2* of unit B become the symmetrical image of Figure 6(E) using the ordinate at $\theta=\pi$ as axis of symmetry, and the voltage wave of Figure 6(D) becomes symmetrical with respect to an axis at $\theta=2\pi$. One further conclusion is that a change in polarity of the control voltage E_C will cause a change in polarity of the voltages induced in the control windings.

Finite Load Resistance

Modes of Operation

It will become apparent in the following that the wave shape of the load current cannot be derived from one and the same equation. For different loadings, basic changes take place in the boundary conditions; as a result, the wave shape of the current will also undergo basic changes. The operation of the reactor within a given set of boundary conditions is called a mode of operation; there are four such modes for normal- and underexcitation and four analogous modes for overexcitation.

Mode 1 operation: For the case of $R_L=0$, the maximum flux swing follows from equation 16. If the flux swing is just 2 Φ_s, the excitation is called normal. The voltage $E_{s,o,m}$ is called the critical no-load saturation voltage and is defined as the voltage which produces a maximum flux swing of 2 Φ_s for $R_L=0$. From equation 16 for $\Phi_{\Delta,m}=2\Phi_s$

$$E_{s,o,m}=2\Phi_s\omega N_L 10^{-8} \tag{18}$$

In the following the load resistance R_L is introduced in the circuit by opening switch *S2* in Figure 2. Similar to linear *R-L* circuits, the steady-state value of the current becomes zero at a point ahead of the crest value of the voltage.

Let the angle at which zero current occurs be $\theta=\alpha$, Figure 7. As in the preceding discussion, the reactors have no impedance at this instant and the load current will abruptly increase until equation 5 is satisfied. One recognizes a spectacular feature of mode 1 operation which consists in the equality of control current ampere-turns and load current ampere-turns as expressed by equation 6 despite existence of load resistance R_L.

$$I_L=I_C N_C/N_L \tag{6}$$

The angle α can be determined by the steady-state premise which requires all quantities to resume their original values after a lapse of 2π radians. Applied to the core flux, it means that the downswing must equal the upswing. The downswing is caused by the voltage e_L across the load winding terminals *X1-X2* shown as the difference between the supply voltage e and the load voltage $I_L R_L$; in the following analysis it is irrelevant whether this difference voltage occurs on unit A or B, and therefore the notations $e_{L,A}$, $e_{L,B}$, have been simplified to e_L. The flux swing follows from an equation similar to equation 13

$$\frac{d\phi_\Delta}{d\theta}\omega N_L\, 10^{-8}=e_L \tag{19}$$

and hence

$$\Phi_{\Delta,m}=\frac{10^8}{\omega N_L}\int_\alpha^\lambda e_L d\theta \tag{20}$$

The flux downswing is seen proportional to the area HCB. In order to make the flux upswing equal, areas $CDJ=HCB$, which relation determines α

$$\int_\alpha^{\alpha+\pi}(E_m \sin\theta - I_L R_L)d\theta=0 \tag{21}$$

and

$$\alpha=\text{arc}\cos\frac{I_L R_L}{E} \tag{22}$$

where

$$E=\frac{2}{\pi E_m} \tag{23}$$

The locus of point B, Figure 7, is a cosine function ($RTBS$) whose crest value is $2E_m/\pi$. This value is identical with the line voltage E measured by a rectifier instrument.

With the ratio $I_L R_L/E$ increasing, point B moves to the left on its cosine locus, and will finally reach the intersection T with the supply voltage e for $\theta=\nu$. A further increase of $I_L R_L/E$ will not cause point B to continue along section T-R of the cosine function because for $\alpha<\nu$ the line voltage is not large enough to produce the load voltage $I_L R_L$. The logical conclusion is that the previously described mode of operation comes to an end at T. For larger values of the ratio $I_L R_L/E$ a different mode of operation occurs and will be discussed later.

The boundary angle ν for the first mode of operation follows from equations 2 and 22

$$e=I_L R_L=E_m \sin\nu=E\cos\nu \tag{24}$$

Figure 9. Normalized characteristic of per-unit load current and load current form factor k_f versus per-unit control ampere-turns; measured values shown by dots

Figure 10 (above). Wave shape of load voltage $I_L R_L$ for mode 2 operation

Figure 12 (right). Angle of retard α versus per-unit control current for mode 2 operation

$$\nu = \text{arc tan } \frac{2}{\pi} = 32.5° \left(\frac{\pi}{180}\right) \tag{25}$$

and

$$\cos \nu = 1/\sqrt{1+\left(\frac{2}{\pi}\right)^2} = 0.844 \tag{26}$$

The boundary condition for mode 1 operation is therefore

$$0 < \frac{I_L R_L}{E} \leq 0.844 \tag{27}$$

The wave shape for the boundary case is shown in Figure 7 by *UTMNPQ*.

In order to express equation 6 more generally, the maximum load current $I_{L,m}$ is introduced. It is that current which flows when the saturable reactor loses all its inductance and therefore is limited by the load circuit resistance R_L only

$$I_{L,m} = E/R_L \tag{28}$$

Dividing both sides of equation 6 by equation 28 and rearranging, the following expression results

$$\frac{I_L}{I_{L,m}} = \frac{I_C N_C}{I_{L,m} N_L} \tag{29}$$

This form of presentation is called normalized form. It has the virtue of describing the performance of any reactor of this category in one and the same graph. In keeping with the terminology used for electric machinery[4], the ratio $I_L/I_{L,m}$ will be called per-unit current, and ratio $I_C N_C / I_{L,m} N_L$ the per-unit ampere-turns. Then the relation between per-unit current and per-unit ampere-turns becomes a straight line, which for identical scales subtends an angle of 45 degrees with the axes. See Figure 9.

Due to air-core reactance, actual measurement will give slightly lower results in the upper part of the range, and somewhat higher values are measured in the lower range because of the finite magnitude of iron-core reactance.

Figure 8 shows an oscillogram of the supply voltage e and the voltage $I_L R_L$ across the load resistance. The per-unit ampere-turns are 0.552 as calculated from $I_C = 0.25$ ampere, $N_C = 200$ turns, $I_{L,m} = 0.153$ ampere, $N_L = 592$ turns. The angle $\alpha = \text{arc cos } 0.552 = 56.5$ degrees $(\pi/180)$. Actual measurement of α, from the oscillogram of Figure 8, is within one degree of the calculated value.

Mode 2 operation: For $I_C N_C / I_{L,m} N_L >$ 0.84 a new mode of operation is obtained as shown in Figure 10. The load voltage $i_L R_L = e$ for $\alpha < \theta < \nu$. Between $\nu < \theta < \alpha + \pi$ the current i_L is constant and follows from equation 6

$$i_L = I_C N_C / N_L \tag{6}$$

The method for calculating the normalized characteristic is shown in Appendix I, and the characteristic itself is plotted as curve *A-B* in Figure 9. For increasing values of per-unit ampere-turns the per-unit load current is bending away from the 45-degree line and finally assumes a horizontal direction. The boundary for mode 2 operation is obviously reached for $\alpha = 0$. The corresponding value for the per-unit ampere-turns follows from Figure 12 as 1.14, and $\nu_1 = 46.4$ degrees. The wave shape at this boundary is shown in Figure 10 by *OBPQRSF-TUVYKX*.

An oscillogram of mode 2 is shown in Figure 11. The circuit constants are the same as for Figure 8, except $I_C = 0.45$ ampere. The per-unit current becomes 0.994 and $\alpha = 16.5$ degrees from Figure 12. A check with the oscillogram will disclose practically the same value for α.

Mode 3 operation: Increasing the per-unit ampere-turns over 1.14, angle α remains zero. The current wave shape is shown in Figure 13 by *OBCDEFGHJK-LMN*, and $I_L R_L$ is the average of area *OBCDEFO*. As in the preceding, areas *BCP* = *CDE* and therefore $I_L R_L$ also equals *OBPCEFO*

$$I_L R_L = E \tag{35}$$

It follows from equation 28 that $I_L = I_{L,m}$ and although the current is changing its wave shape, the average value remains constant. The value of i_L in its flat region is still determined by equation 6. Increasing the control current will bring i_L to its boundary

$$\frac{I_C N_C}{N_L} = i_L = \frac{E_m}{R_L} \tag{36}$$

The maximum per-unit control ampere-turns for mode 3 operation therefore are

$$\frac{I_C N_C}{I_{L,m} N_L} = \frac{\pi}{2} \tag{37}$$

which is the upper boundary for mode 3

Figure 11 (left). Oscillogram of supply voltage e and load voltage $I_L R_L$ for mode 2 operation

Figure 13 (right). Wave shape of load voltage $I_L R_L$ for mode 3 operation

Figure 14. Oscillogram of supply voltage e and load voltage I_LR_L for mode 3 operation

operation. While the average value of the load current remains constant (*B-C*, Figure 9) during mode 3 operation, the rms value of the load current changes.

An oscillogram of mode 3 operation is shown in Figure 14. The per-unit control ampere-turns are 1.32. The current I_L is measured as 0.153 ampere which is identical with the measured value of $I_{L,m}$.

Mode 4 operation: By increasing the per-unit ampere-turns over $\pi/2$, the circuit acts as though no iron were present in the reactor. The load current is sinusoidal and its value remains $I_{L,m}$. Its representation in the normalized characteristic of Figure 9 is a horizontal line to the right of *C* at the level of unity. In contrast to mode 3 operation, where the rms value of the load current is changeable, the rms value of the load current during mode 4 operation is constant.

Conclusion From Normalized Curves

Power gain: The normalized characteristics can be written in the following form

$$y=f(x) \tag{38}$$

where

Figure 16. General characteristic of load current I_L versus referred control current I_CN_C/N_L

$$y=\frac{I_L}{E/R_L} \tag{39}$$

and

$$x=\frac{I_CN_C}{I_{L,m}N_L} \tag{40}$$

The power gain G_p is defined as the ratio of output power P_o divided by input power P_i

$$G_p=\frac{I_L^2R_L}{I_C^2R_C}k^2{}_f \tag{41}$$

where k_f is the form factor of the load current. Substituting for I_L from equation 39 for I_C from equation, 40, and using equation 28 one obtains

$$G_p=\left[\frac{f(x)}{x}\right]^2\frac{R_L}{R_C}\frac{N_C^2}{N_L^2}k^2{}_f \tag{42}$$

The function $(f(x)/x)^2$ can be calculated from the normalized characteristic (Figure 9) and is plotted on double logarithmic scales (Figure 15). The form factor k_f has been plotted in Figure 9 from experimental data. Thus, one notes that the power gain is constant for per-unit ampere-turns up to 0.844 (point *A*), then drops to B_2 $(1/1.14^2=0.77)$, and finally declines at the rate of 40 decibels per dec-

Figure 15 (left). Gain functions $f(x)/x$ and $[f(x)/x]^2$ versus per-unit control current

Figure 17 (below). General characteristic of load current I_L versus ratio E/R_L

Figure 18. Saturation voltage ratio ξ versus per-unit load current

ade. (The extension of B_1C_1 goes through the point with the co-ordinates 1 and 1.) It is also apparent that the power gain for mode 1 operation is equal to the ratio of load resistance R_L to control circuit resistance R_C when referred to the load winding. It is furthermore important to note from equation 42 that the permeability of the core material does not affect the power gain. A typical value for power gain is 100.

Current gain: The current gain G_i is defined as the ratio of the load current I_L over the control current I_C

$$G_i = \frac{I_L}{I_C} = \frac{f(x)}{x} \frac{E/R_L}{I_{L,m}N_L/N_C} = \frac{f(x)}{x} \frac{N_C}{N_L} \qquad (43)$$

The function $f(x)/x$ also is plotted in Figure 15. It can be seen that the current gain is constant for mode 1 operation and equals the turn ratio N_C/N_L. For higher modes of operation the current gain falls off to $1/1.14 = 0.88$ at point B_1 and then drops at the rate of 20 decibels per decade.

Voltage gain: The voltage gain G_e is defined as the ratio of load voltage to control voltage. If R_C is the total resistance in the control circuit the voltage gain becomes

$$G_e = \frac{I_L R_L}{I_C R_C} = \frac{f(x)}{x} \frac{N_C}{N_L} \frac{R_L}{R_C} \qquad (44)$$

The function $f(x)/x$ is again available from Figure 15.

Parametric representation: If characteristics are to be obtained with the voltage E and the load resistance R_L as parameters, these curves can be derived directly from the normalized characteristics by multiplying x and $f(x)$ by $I_{L,m} = E/R_L$ and assigning discreet values to E/R_L. These curves are plotted in Figure 16 and the boundaries for the various modes of operations are indicated (tan 32.5 degrees $= 2/\pi$, tan 41.3 degrees $= 1/1.14$, tan 79.6 degrees $= 0.84/1-0.84$). For a given $I_C N_C/N_L$ a line under 79.6 degrees intersects the 45-degree line OA at the boundary between mode 1 and 2 operation. Lines OB and OC are boundaries between mode 2 and 3, and mode 3 and 4 operation. It should be observed that no dimensions are assigned to the axes and parameters, because any dimension derived from a consistent system is suitable. Furthermore, scaling up and down both axes and the parameters by the same factor is permissible. Therefore Figure 16 represents the characteristics of any saturable reactor of the category in question.

For the control current as a parameter, one obtains the characteristics shown in Figure 17. From equations 38, 39, and 40, one obtains

$$I_L = \frac{E}{R_L} f(x) \qquad x = \frac{I_C N_C}{E/R_L N_L}$$

With $I_C N_C/N_L$ as parameter and E/R_L as variable, the new characteristics can be plotted; $f(x)$ is available from Figure 9. The lines under the following angles indicate boundaries: tan 32.5 degrees $= 2/\pi$, tan 40.3 degrees $= 0.84$, tan 82.3 degrees $= 1/(1.14-1)$. Here too, consistent systems of units and their multiples can be assigned to the axes and parameters. These curves represent the operation of any saturable reactor of the specified category within the limits previously stated.

The Overexcited Saturable Reactor Example

Boundary

All previous calculations and conclusions were based on the assumption of normal- or underexcited operation as previously defined. For zero load resistance, the critical no-load saturation voltage $E_{s,o}$ (equation 18 for $E_{s,o,m}$) will just produce a flux swing equal to $2\Phi_s$. An increase of line voltage over $E_{s,o}$ will result in a second zone of saturation along the lower branch of the magnetization line with subsequent change of wave shape and hence change in the mode of operation. With the introduction of load resistance R_L some of the line voltage is now taken up by the load resistance and only the remainder is left for a flux swing. Consequently, an increase of line voltage over $E_{s,o}$ can be permitted until the flux swing reaches $2\Phi_s$. The voltage at which this

Figure 19. Normalized characteristics for normal-, under-, and overexcitation

flux swing is obtained is designated by E_s and is called the critical saturation voltage in the presence of load resistance. It is determined in Appendix II; the ratio $E_s/E_{s,o}$ as function unit load current is shown in Figure 18.

The full significance $E_s/E_{s,o}$ becomes apparent when the axes and parameters of the graph in Figure 17 are multiplied by $R_L/E_{s,o}$. This new graph is shown in Figure 19. It can be seen that the ratio $E/E_{s,o}$ can be increased over unity for increasing control ampere-turns (namely up to the dashed curve ABC) without change of mode of operation. The points on the dashed curve ABC signify ratios $E_s/E_{s,o}$ which satisfy equation 48 and therefore indicate normal excitation. The area to the left of ABC includes underexcited operation, the area to the right overexcited operation.

Overexcited Operation, Mode 1

The current will start at α, as shown in Figure 20, so that equation 6 is satisfied

$$i_L = I_C N_C / N_L \tag{6}$$

For $\alpha < \theta < \vartheta$ the voltage e_L causes a flux swing which is proportional to the area between the sine wave and the load voltage $i_L R_L$. In the case shown in Figure 20, the maximum flux swing is reached at $\theta = \vartheta$. For $\theta > \vartheta$ the lower branch of the magnetization line is reached and the reactor loses all inductance. The load resistance then finds itself exposed to the full line voltage and the load current increases accordingly. For $\vartheta < \theta < \lambda$ the load voltage is equal to the line voltage. At $\theta = \lambda$ the vertical part of the magnetization line is reached and hence the reactor again exhibits inductance. The load current again follows equation 6 until the flux upswing as shown by area EFR, equals the flux downswing indicated by area $BCDQ$.

An oscillogram of overexcited operation, mode 1, is shown in Figure 21. The control current is 0.25 ampere as in the oscillogram of Figure 8. Voltage $E_{s,o} = 42.8$ volts, voltage $E = 54$ volts, and resistance $R_L = 280$ ohms. The calculated angle (67 degrees) and the measured-angle are within normal tolerances of measurement.

The load current can be determined as shown in Appendix III

$$I_L = \frac{E_m}{R_L}\left[\sin\lambda + \frac{1}{\pi}(2\cos\alpha + \cos\lambda - \pi\sin\lambda - \cos\lambda)\right] = \frac{E}{R_L}\cos\alpha \tag{55}$$

One arrives at the rather unexpected result that for mode 1 operation the expression for the load current is the same for normal and underexcitation (equation 22), as well as for overexcitation (equation 55). The graph in Figure 19 covers the entire range of excitation and the effect of any circuit parameter is apparent. This graph gives a complete description for the operation of any saturable reactor of the defined category for every mode of operation in the normal and underexcited state, and for mode 1 operation in the overexcited state. Higher modes of operation in the overexcited state have hardly any practical significance and are not shown in Figure 19.

Mode 1 operation occurs in the area between the straight lines OC and AF. The area is subdivided by the curve ABC in the left-hand section corresponding to normal- and underexcitation, and the right-hand, overexcited part. Mode 2 operation occurs between lines OC and OD, while modes 3 and 4 operation occurs along line OD. The underexcited range for modes 2, 3, and 4 is limited by the characteristic with the parameter 1.38.

The overexcited characteristic for the parameter O is a straight line under 45 degrees; for higher parameters the characteristics are slightly curved. The intersection OD with a line subtending an angle of 83.2 degrees gives the border point between modes 3 and 4 operation and mode 2 operation, for a given $E/E_{s,o}$.

Example

A saturable reactor similar to Figure 2 should deliver 2 amperes average into the 5.5-ohm coil of a voltage regulator when the primary current is 500 amperes. The primary current may vary from 500 to zero, the supply voltage is subject to ±25-per cent variation. Determine the basic design parameters.

The coil of the voltage regulator requires direct current and hence it is put directly in series with the ammeter in Figure 2. The rectifier resistance may be 20 per cent of the load resistance, and the resistance of the load coils of the saturable reactor 10 per cent. The load resistance R_L becomes

$$R_L = 5.5 + 1.1 + 0.55 = 7.15 \text{ ohms}$$

In order to obtain linearity between primary current I_C and load current I_L overexcitation must be avoided. According to Figure 19 the highest permissible $E/E_{s,o} = 1$. If the design center voltage is called E_d, then

$$E_{min} = 0.75 E_d \tag{56}$$

and

$$E_{max} = 1.25 E_d \tag{57}$$

The minimum voltage ratio $E_{min}/E_{s,o}$

$$\frac{E_{min}}{E_{s,o}} = \frac{E_{min}}{E_{max}} = \frac{0.75}{1.25} = 0.6 \tag{58}$$

The parameter for the curves of Figure 19 has to be determined so as to provide a horizontal characteristic over the whole range of voltage fluctuation. The limiting line OC has a slope of 1/1.18 as shown in Figure 17. The intersection of line OC Figure 19 with the ordinate $E_{min}/E_{s,o} = 0.6$ (equation 58) occurs at $0.6/1.18 = 0.508$. Hence

$$E_{s,o} = E_{max} = \frac{I_L R_L}{0.6/1.18} = \frac{2 \times 7.15}{0.508} = 28.1 \text{ volts} \tag{59}$$

and from equation 57

$$E_d = \frac{E_{max}}{1.25} = 22.4 \text{ volts} \tag{60}$$

It follows that the core design has to aim at a no-load saturation voltage of $28.1/0.9 = 31$ volts rms, the supply voltage for the load circuit is $22.4/0.9 = 24.9$ volts rms ±25 per cent, and the turn ratio (equation 6)

$$\frac{N_L}{N_C} = \frac{2}{500} = \frac{1}{250} \tag{61}$$

Figure 20 (left). Wave shape of load voltage $I_L R_L$ for mode 1 operation, overexcited

Figure 21 (right). Oscillogram of supply voltage e and load voltage $I_L R_L$ for mode 1 operation, overexcited

With this basic data, the reactors may be calculated in much the same manner as any ordinary transformer.

Appendix I

The average load current I_L follows from

$$I_L=\frac{1}{\pi}\int_{\alpha}^{\alpha+\pi} i_L d\theta=\frac{1}{\pi}\left[\int_{\alpha}^{\gamma} i_L d\theta+\frac{I_C N_C}{N_L}(\alpha+\pi-\gamma)\right]$$

$$=\frac{E}{R_L}\frac{\cos\alpha-\cos\gamma}{2}+\frac{I_C N_C}{N_L}\left(1-\frac{\gamma-\alpha}{\pi}\right) \quad (30)$$

In per-unit notation

$$\frac{I_L}{I_{L,m}}=\frac{\cos\alpha-\cos\gamma}{2}+\frac{I_C N_C}{I_{L,m} N_L}\left(1-\frac{\gamma-\alpha}{\pi}\right) \quad (31)$$

Next, γ is determined

$$\sin\gamma=\frac{CW}{MN}=\frac{\frac{I_C N_C}{N_L}R_L}{E_m}=\frac{2}{\pi}\frac{I_C N_C}{I_{L,m} N_L} \quad (32)$$

As in the preceding paragraphs the flux swing is proportional to area *CMD*. For steady-state operation areas *CMD* and *DEF* are equal, hence

$$\int_{\gamma}^{\alpha+\pi}\sin\theta d\theta-(\alpha+\pi-\gamma)\sin\gamma=0 \quad (33)$$

and

$$\cos\alpha+\cos\gamma-(\alpha+\pi-\gamma)\sin\gamma=0 \quad (34)$$

This is a transcendental equation which is graphically solved, using γ from equation 32. The solution as function of the per-unit load current is shown in Figure 12. The per-unit load current now is obtainable from equation 31 and the normalized characteristic plotted in Figure 9.

Appendix II

The criterion for normal excitation is

$$\Phi_{\Delta,m}=2\Phi_s \quad (45)$$

Let

$$\xi=E_s/E_{s,o} \quad (46)$$

The flux swing follows from equation 20. The voltage e_L is seen in Figure 7

$$\Phi_{\Delta,m}=\frac{10^8}{\omega N_L}\int_{\alpha}^{\lambda}(e_L-I_L R_L)d\theta$$

$$=\frac{10^8}{\omega N_L}[E_m(\cos\alpha-\cos\lambda)-I_L R_L(\lambda-\alpha)] \quad (47)$$

Substituting into equation 45 from equations 47, 18, and 46

$$1/\xi=\cos\alpha-\cos\lambda-\frac{2}{\pi}\left[\frac{I_L R_L}{E}(\lambda-\alpha)\right] \quad (48)$$

ξ can now be plotted as a function of the per-unit load current, since α follows from equation 22, and is shown in Figure 18.

Appendix III

First, angle α will be determined. The flux swing which is represented by the area *EFR* equals $2\Phi_s$, therefore equals the area of a quarter sine wave with the amplitude $E_{s,o,m}$.

$$\text{area } EFR=i_L R_L(\pi+\alpha-\lambda)-\int_{\lambda}^{\alpha+\pi}\sin\theta d\theta=i_L R_L(\pi+\alpha-\lambda)-E_m(\cos\alpha+\cos\lambda) \quad (49)$$

and

$$i_L R_L=E_m\sin\lambda \quad (50)$$

Substituting equation 50 in 49 one obtains

$$\text{area } EFR=E_m[(\pi+\alpha-\lambda)\sin\lambda-\cos\alpha-\cos\lambda]=E_{s,o,m}\int_0^{\pi/2}\sin\theta d\theta=E_{s,o,m} \quad (51)$$

The angle α now can be determined graphically for any voltage ratio $E/E_{s,o}$.

Next the load current is calculated; it can be seen to consist of a constant part *B-F* and a sinusoidal part *CDE*

$$I_L=\frac{E_m}{R_L}\left[\sin\lambda+\frac{1}{\pi}\int_{\vartheta}^{\lambda}\sin\theta d\theta-\frac{1}{\pi}(\lambda-\vartheta)\sin\lambda\right]=\frac{E_m}{R_L}\left\{\sin\lambda+\frac{1}{\pi}[(\cos\vartheta-\cos\lambda+(\vartheta-\lambda)\sin\lambda)]\right\} \quad (52)$$

In order to solve this equation, one remembers that the flux upswing equals the flux downswing, hence areas $EFR=BCDQ$

$$\text{area } BCDQ=E_m\int_{\alpha}^{\vartheta}\sin\theta d\theta-i_L R_L(\vartheta-\alpha)=E_m(\cos\alpha-\cos\vartheta)-i_L R_L(\vartheta-\alpha) \quad (53)$$

Equating equations 49, 50, and 53, one obtains

$$\cos\vartheta+(\vartheta-\alpha)\sin\lambda=2\cos\alpha+\cos\lambda-\pi\sin\lambda \quad (54)$$

Substituting equation 54 in equation 52

$$I_L=\frac{E_m}{R_L}[\sin\lambda+\lambda(2\cos\alpha+\cos\lambda-\pi\sin\lambda-\cos\lambda)]=\frac{E}{R_L}\cos\alpha \quad (55)$$

α is obtainable from equation 51.

Appendix IV. List of Symbols

B = flux density in gauss
B_s = saturation flux density, in gauss
e = instantaneous supply voltage, in volts
E = average rectified supply voltage, in volts
E_m = amplitude of supply voltage, in volts
$e_{L,A}, e_{L,B}$ = instantaneous voltage across load winding of reactor *A* or *B*, respectively, in volts
e_L = instantaneous voltage across both load windings, in volts
E_C = voltage of control source, in volts
$e_{C,A}$, $e_{C,B}$ = instantaneous voltage across control winding of reactor *A* or *B* respectively, in volts
$E_{s,o,m}$ = amplitude of no-load saturation voltage, in volts
$E_{s,o}$ = average rectified no-load saturation voltage, in volts
E_s = average rectified saturation voltage, in volts
E_d = design center voltage, rectified average, in volts
E_{max} = highest permissible overvoltage, rectified average, in volts
E_{min} = lowest permissible undervoltage, rectified average, in volts
f = frequency, cycles per second
$f(x)$ = ordinates of normalized characteristic of Figure 9, unity
F_A, F_B = magnetomotive force in core *A* or *B* respectively, in gilberts
G_e = voltage gain, unity
G_i = current gain, unity
G_p = power gain, unity
H = magnetic intensity, oersted
i_L = instantaneous current in load resistor R_L, in amperes
I_L = average rectified load current, amperes
$I_{L,m}$ = average rectified maximum load current (equation 28), in amperes
$i_{L,A}$, $i_{L,B}$ = instantaneous current in load winding of reactor *A* or *B*, respectively in amperes
I_C = average value of control current, in amperes
k_f = form factor of load current, unity
L = inductance of load winding, in henrys
L_C = fictitious inductance of the outer control circuit, in henrys
N_C, N_L = number of turns of one control winding or one load winding, respectively
P_i = power supplied to control circuit, in watts
P_o = power delivered to load resistor R_L, in watts
R_C = resistance of the entire control circuit, in ohms
R_L = load resistance, in ohms
t = time, seconds
x = per-unit control ampere-turns
y = per-unit load current
α = angle of retard, in degrees or radians
γ = phase angle shown in Figure 10, in degrees or radians
γ_1 = boundary angle between mode 2 and 3, in degrees or radians
ϑ = phase angle at which saturation occurs (Figure 20), in degrees or radians
θ = phase angle, degrees or radians
λ = phase angle in Figure 7, in degrees or radians
ν = angle of retard at boundary between mode 1 and 2, in degrees or radians
ξ = saturation voltage ratio (equation 46), units
π = 3.14159
ϕ_A, ϕ_B = instantaneous magnetic flux in core of reactor *A* or *B*, respectively, in maxwells
Φ_s = saturation flux, in maxwells
ϕ_Δ = instantaneous value of flux swing, in maxwells
$\Phi_{\Delta,m}$ = maximum value of flux swing, in maxwells
ω = angular velocity of time vector, radians per second

Synopsis: The performance of the half-wave circuit under the conditions of high external control-circuit impedance and no rectifier leakage is taken as the basis for the steady-state analysis of the self-saturating magnetic amplifiers. Transfer curves for the basic circuit are determined by a combination of idealized and no-load methods, each applied in the appropriate region of operation, and the results extended to the full-wave and doubler circuits. Rectifier leakage and control-circuit impedance effects are computed for each type of circuit. Transfer curves for all three circuits under practical operating conditions are obtained by correcting the basic curves for these effects. Satisfactory results are obtained on test amplifiers containing orthonik and hypersil cores.

THE purpose of this paper is to describe a method for determining the steady-state performance of the basic self-saturating magnetic amplifier circuits. Consideration of magnetic core loop width, rectifier forward resistance, and rectifier reverse (or leakage) current flow is essential to the investigation of all self-saturating amplifier circuits. The latter factors have been generally neglected in recent papers.

This paper considers the performance of the half-wave circuit, with no rectifier leakage and constrained magnetization (no circulating alternating current in the control winding), as basic for all self-saturating circuits. To determine the actual transfer curve for each type of circuit, half-wave, full-wave, and doubler, when rectifier leakage and control alternating currents are present, corrections are applied to the curve of the basic circuit. The term transfer curve, as used in this paper, refers to the plot of average load current versus d-c control current with fixed resistive load and a-c supply voltage.

Magnetic Core Characteristics

When a magnetic material is magnetized in a cyclic and symmetrical manner, the relationship between flux density and field intensity is defined by a family of symmetrical loops. For many purposes the locus of the end points, which essentially coincides with the d-c magnetization curve, may be taken as a satisfactory approximation to the actual relationship between flux density and field intensity. When the magnetization process is asymmetrical, no single magnetization curve can be defined.

In the case of the more sensitive magnetic materials, when the maximum core flux approaches saturation value during cyclic operation, the upper branch of the asymmetrical loop traversed coincides with the upper branch of a large symmetrical loop. The situation is illustrated in Figure 1(A). Since both the upper and lower end points of the asymmetrical loops lie on this curve, the upper branch of a large symmetrical loop can be taken as an equivalent magnetization curve when the core saturates during the cycle. When the flux variation is symmetrical, or nearly symmetrical without large cyclic saturation, the d-c magnetization curve can be used, Figure 1(C). In computing the transfer curves for the self-saturating amplifiers, the magnetic characteristics of the core are assumed to be represented by the upper branch of a large symmetrical loop when the cyclic core saturation is large, and by the d-c magnetization curve when the flux variation is nearly symmetrical (in the region of minimum load current). In the intermediate region, illustrated in Figure 1(B), an additional assumption is made.

In computing amplifier performance, a knowledge of the relationship between core flux and ampere turns is required. The core-flux density is not uniform across its sectional area, and the total core flux, corresponding to a given number of impressed ampere turns, is not readily determinable. It is, therefore, necessary to

Paper 50-206, recommended by the AIEE Electronics Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 2–5, 1950. Manuscript submitted May 11, 1950; made available for printing August 7, 1950.

Edward J. Smith is Research Fellow at the Microwave Research Institute, Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

The author expresses his gratitude to Professors M. Liwschitz-Garik and E. Weber of the Polytechnic Institute of Brooklyn for their generous guidance and encouragement in all phases of the research work, and to Mr. A. Schwartz of the Microwave Research Institute who obtained much of the experimental data for this paper.

The study of magnetic amplifiers is being undertaken at the Microwave Research Institute under the sponsorship of the Office of Naval Research.

have available magnetic data which give the relationship between an equivalent uniform flux density and a field intensity based upon the mean length of the core. That is, it is necessary to have magnetic data which apply for the particular material and core shape.

Rectifier Forward Resistance

The forward resistance of dry-disk rectifiers (resistance when current flows in the forward direction), as used in magnetic amplifiers, decreases as the forward current increases. Consideration of the variable nature of the forward resistance during a cycle greatly complicates the already difficult problem, and is not really necessary in practical circuits. Then it is assumed that the rectifier has an equivalent constant forward resistance over a cycle. Furthermore, it has been found possible to assume a constant forward resistance for operation over the entire transfer curve.

For a particular transfer curve in regions of large positive control current, each load mesh consists essentially of the load resistance in series with the rectifier and applied alternating voltage. (The self-saturating circuits are shown in Figure 2.) The effect of forward rectifier resistance upon average load current is therefore maximum in this region. As long as operation continues above the knee of the transfer curve, the change in average load current is relatively small and the change in rectifier forward resistance is even smaller. Below the knee of the transfer curve, the inductance of the reactor dominates and relatively large changes in circuit resistance have little affect upon average load current. Consequently, it seems very reasonable to expect that, if the equivalent rectifier forward resistance is selected under conditions similar to the region of its maximum importance, good results will be obtained over the entire transfer curve.

The previous considerations suggest the direct measurement of the rectifier equivalent forward volt-ampere characteristic by an a-c method. Figure 3 shows the test circuit arrangement and measured characteristic for a particular selenium disc rectifier. Briefly, a sinusoidal voltage is applied to the rectifier, and the average current (direct) is measured for varying values of alternating voltage. Under these conditions, the operation of the rectifier in an actual amplifier circuit above the knee of the transfer curve is very closely duplicated. The characteristic curve is plotted as average applied voltage (over a half-cycle) versus average rectifier current. For prescribed values of applied alternating voltage and load resistance, the ultimate average load current (per mesh) is determined by constructing a load line in the conventional manner and observing its intersection with the measured curve. The equivalent forward resistance then is given by

$$R_f = \frac{V_{avg}}{I_{avg}} \tag{1}$$

in which the values of V_{avg} and I_{avg} are obtained from the intersection. A curve of equivalent rectifier resistance as a function of average current is shown in Figure 4. The duplication of measured points in certain regions is the result of remeasurements at later dates. Their somewhat scattered disposition gives an idea

Nomenclature

A = Core cross-sectional area, square inches
B = Flux density, lines per square inch
B_c = Premagnetization flux density, lines per square inch
B_m = Maximum value of flux density variation, lines per square inch
B_m' = Equivalent maximum value of flux density variation, lines per square inch
B_s = Saturation flux density, lines per square inch
D_m = Deviation from linearity of H_m, ampere turns per inch
E = Reactor voltage, volts
E_f = Reactor voltage during forward conduction, volts
E_r = Reactor voltage during reverse conduction, volts
H, $(\boldsymbol{H})$ = Core magnetization (period average), ampere turns per inch
H_c = D-c control magnetization, ampere turns per inch
H_L, $(\boldsymbol{H}_L)$ = Load magnetization (period average), ampere turns per inch
H_m = Magnetization corresponding to B_m, ampere turns per inch
i = Load current, amperes
i_c = Control current, amperes
I = Average load current in basic half-wave circuit, amperes
I_{cl} = Control current equivalent of leakage demagnetization, amperes
I_{EX} = Control current equivalent of control coupling demagnetization, amperes
I_f = Average forward load current, amperes
I_{Ll} = Load current equivalent of leakage demagnetization, amperes
I_{MC} = Control current equivalent of resistance magnetizing effect in half-wave circuit, amperes
I_{po} = Postsaturation load current, amperes
I_{pr} = Presaturation load current, amperes
I_r, (I_{rh}) = Average reverse load current (half period), amperes
I_s = Ultimate average forward load current, amperes
I_T = Total average load current, amperes
l_m = Mean path length of magnetic flux, inches
N = Turns on load winding
N_c = Turns on control winding
r = Load winding resistance, ohms
r_c = Control circuit resistance, ohms
r_c' = Control circuit resistance referred to load circuit, ohms
R = Load mesh resistance, ohms
R_f = Forward rectifier resistance, ohms
R_L = Load resistance, ohms
R_r = Reverse rectifier resistance, ohms
R_T = Forward load mesh resistance, ohms
t = Time, seconds
t_0 = Time of start of forward current flow, seconds
t_1 = Time of end of forward current flow, seconds
t_s = Time of core saturation, seconds
$V_{D\text{-}C}$ = D-c control circuit voltage, volts
V_m = Maximum value of a-c applied voltage, volts
V_m' = Maximum value of effective a-c applied voltage, volts
V_r, (V_r) = Reverse rectifier voltage (average), volts
Φ = Core flux, lines
Φ_c = Premagnetization flux, lines
Φ_c' = Premagnetization flux in presence of rectifier leakage, lines
Φ_m = Maximum value of flux variation, lines
Φ_s = Saturation flux, lines
σ = Ratio of Φ_s to Φ_m
ω = Angular frequency of supply, radians per second

Subscripts 1 and 2 used in combination with certain of the above symbols refer to meshes 1 and 2, respectively.

as to the constancy of rectifier properties which may be expected. From measured transfer curves of experimental hypersil and orthonik amplifiers, values of equivalent rectifier forward resistance necessary to produce the observed values of ultimate average load current were computed. These points, shown as circles in Figure 4, indicate reasonable agreement with the measured characteristic.

Basic Half-Wave Circuit

Under conditions of constrained magnetization and no rectifier reverse current flow, the initial cyclic (presaturation) flux density is determined solely by the d-c control current and the hysteresis loop. Above the knee of the transfer curve the presaturation flux density B_e is assumed to be specified by the upper branch of a large symmetrical loop. For more sensitive materials a saturation flux density B_s can be defined. The mesh equations are

$$V_m \sin \omega t = Ri + NA\frac{dB}{dt} \tag{2}$$

$$V_{D-C} = r_d i_e \tag{3}$$

The presaturation flux density is determined by control circuit magnetization

$$H_e = \frac{N_d i_e}{l_m} \tag{4}$$

The problem is simplified further by assuming that the actual cyclic process can be approximated by initial change in flux without load current flow (up to saturation B_s), followed by current flow with no further change in flux.[1] The actual current wave is replaced by one having zero value until saturation is reached at time t_s, and then having sinusoidal form until time $(1/2)T$. Thereafter, the load current remains at zero value during the negative half-cycle of applied voltage. The saturation angle is given by

$$\omega t_s = \cos^{-1}\left[1-\left(\frac{B_s-B_e}{B_m}\right)\right] \tag{5}$$

and the average load current is

$$I = I_s\left[1-\left(\frac{B_s-B_e}{2B_m}\right)\right] \tag{6}$$

in which

$$B_m = \frac{V_m}{\omega NA}, \quad I_s = \frac{V_m}{\pi R_T}$$

The results given by such an idealized method are generally satisfactory above the knee of the transfer curve; below the knee of the transfer curve, the calculated curve is too steep. In the latter region the presaturation current flow cannot be neglected, nor can the presaturation flux be obtained from the upper branch of the large symmetrical loop. Results for a hypersil half-wave amplifier are shown in Figure 5.

When the core saturation is small, the inductance of the reactor predominates and the load current is essentially independent of load resistance. The rms voltage drop across the load at the minimum point is usually less than 5 per cent of the supply voltage in practical amplifiers. The assumption of zero circuit resistance simplifies the mathematics and permits solution for load current by direct graphic integration or by analytical methods. The d-c or normal magnetization curve can be used in this region. Such procedures undoubtedly lead to satisfactory results, but are somewhat tedious and special. A more general and rapid method is sought. In particular, it is the aim to focus attention upon the most critical regions of the transfer curve, and to accept less accuracy for the less important regions. The region of minimum load current is such a critical region; the region to the left does not represent a usual operating region, and is not of great importance. With zero forward mesh resistance, the current flows in a positive direction over the entire cycle and becomes zero at the start of each positive half-cycle of applied voltage. The average value of load winding magnetizing force is

$$H_L = H - H_e \tag{7}$$

in which H is the average value of total core magnetization. When the flux variation is symmetrical.

$$H = 0, \text{ and } H_L = -H_e \tag{8}$$

independent of the shape of the magnetization curve. When the minimum current region of the transfer curve corresponds to operation along a portion

Figure 4 (left). Rectifier forward a-c resistance characteristic (10-disk selenium rectifier). The crosses denote measured values; the circles denote values computed from measured transfer curves

Figure 5 (right). Comparison of measured and computed transfer curves for a half-wave circuit (hypersil cores with constrained magnetization)

of the magnetization curve which is essentially linear, symmetrical flux variation occurs at the point of minimum load current, and

$$H_{L\,(min)} = |H_c| = H_m \tag{9}$$

H_m is the magnetizing force corresponding to B_m.

When symmetrical flux variation does not occur in a linear region of the transfer curve, the minimum point occurs when the flux variation is shifted in the positive B direction. Since operation near the minimum point does not involve large core saturation, the magnetization curve can usually be represented in this region by

$$H = k_1 B + k_3 B^3$$

For this representation there obtains[2]

$$H_L = H_m + D_m S_1(\sigma) \tag{10}$$

where

$$\sigma = \frac{B_c}{B_m}, \text{ and } S_1(\sigma) = 3(\sigma^3 + 1.5\sigma + 0.5)$$

and D_m is the deviation of the magnetization curve from linearity at B_m. The minimum average value of load current is found to occur for $\sigma = -3/4$; from equation 10

$$H_{L(min)} = H_m - \frac{3}{16} D_m \tag{11}$$

and the corresponding control direct current required is found from the magnetization curve from

$$|B_c| = \frac{3}{4} B_m \tag{12}$$

This should be compared with

$$|B_c| = B_m$$

in the case of linear operation. Higher power terms could be added to the curve representation, but usually are not necessary because large saturation does not occur.

The minimum point of the transfer curve now can be determined readily by inspection. A straight line drawn from the origin tangent to the knee of the magnetization curve divides this curve into a linear region and a nonlinear region. If the maximum symmetrical flux variation (B_m) falls below the knee of the magnetization curve, linear operation is assumed and equation 9 is applied. Above the knee the value D_m is measured as the horizontal distance between the straight line and the magnetization curve at B_m; the minimum point is determined by applying equations 11 and 12.

A straight line drawn from the minimum point tangent to the knee of the transfer curve, computed by the aforementioned idealized method, closely approximates the steep portion of the transfer curve. To the left of the minimum point the transfer curve is computed from equation 10. When the hysteresis loop of the material approaches a rectangular shape, the relation[3]

$$H_L = |H_c| \tag{13}$$

more closely describes the behavior in this region. Computed transfer curves for a test hypersil amplifier, shown in Figure 5, agree closely with measured curves. Discrepancies in the region of the knee of the upper curve are due primarily to rectifier leakage and will be considered later. Similar agreement was found for a test orthonik amplifier.

Full-Wave and Doubler Circuits

For the case of constrained magnetization, the steady-state transfer curve for the full-wave or doubler circuit is primarily the sum of the transfer curves of the individual half-wave meshes. Differences occur due to mesh coupling through the common load resistor, and rectifier leakage current flow. If rectifier leakage is neglected, for the moment, and if it is assumed that forward current flows in each mesh only during the corresponding positive half-cycle of applied voltage, then no interaction between meshes occurs and the average value of load current on a per-reactor basis is identical for the three types of circuits. When the hysteresis loop of the core material approaches rectangular form, mesh current truly flows only during the positive half-cycle of voltage.

This is seen to be the case for the orthonik amplifiers as shown by the oscillograms of Figure 6.

When the hysteresis loop does not approach this rectangular form, the forward mesh current continues to flow after the applied voltage becomes zero. For such

materials there exists the possibility, in the case of the full-wave and doubler circuits, of simultaneous forward current flow in two meshes over a portion of the cycle. Interaction occurs, and the average load current per reactor is not exactly the same for all three circuits. Although the forward current in one mesh may continue flowing well into the negative half-cycle, the effect of this current overshoot upon average load current is only in proportion to the ratio of overshoot area under the load voltage wave to the area under the applied voltage wave from the start of a positive cycle to saturation.[3] The overshoot area is the area under the load voltage wave of the half-wave mesh from time $(1/2)T$ until the load voltage becomes zero. The saturation point is arbitrarily defined as the point at which the mesh current increases with maximum rate. Oscillograms of load current for hypersil amplifiers for an intermediate value of core presaturation are given in Figure 7. Reference to the oscillogram for the half-wave circuit shows the positive load voltage to persist for approximately 60 degrees into the next half-cycle; nevertheless, the overshoot area under this curve is small as compared with the area under the applied voltage wave before saturation.

In order to measure the effect of mesh interaction without the additional complication of rectifier leakage, the dry-disc rectifiers were replaced by vacuum or mercury vapor tubes. Transfer curves for the individual half-wave meshes were measured and their sum determined by adding individual mesh load currents corresponding to various values of control current; transfer curves for the composite full-wave circuits then were measured and compared with the previous curves. The results for the orthonik amplifiers, given in Figure 8, show the effect of mesh interaction to be negligible. The results for the hypersil amplifiers, given in Figure 9, show a small and approximately uniform shift of the curve for the composite amplifier to the right. This may be due partially to unbalance in the individual meshes. The shape of this transfer curve does not differ appreciably from the shape of the curve of the half-wave meshes; the shape of the curve is, above all, the more important feature.

A corresponding curve for the full-wave circuit using selenium disc rectifiers also is shown in each case. (Total forward mesh resistance at ultimate saturation and load resistance were maintained fixed for each material by adjusting resistors in series with the reactors.) In each case, this curve deviates from the previous two curves by a large amount, especially in the region of the knee, and illustrates very clearly the large effect of rectifier leakage. Therefore, it is concluded that mesh interaction is of negligible importance as compared with rectifier leakage effects when resistive loads and reasonably sensitive (but by no means ideal) materials are employed.

Rectifier Leakage Effects

Rectifier leakage current flow modifies the operation by contributing directly to the average load current, and by demagnetizing the core. The first effect is small and usually negligible, but the demagnetizing effect can not generally be neglected. Only the effect of rectifier leakage on the shape of the transfer curve will be considered.

In the steady-state case the flux is periodic and the time integral of reactor inductive voltage drop over a period of applied voltage is zero. If E_f and E_r denote respectively the inductive voltage across the reactor load winding during the intervals of forward (t_0 to t_1) and reverse (t_1 to t_0+T) rectifier current flow, then

$$\int_{t_0}^{t_1} E_f dt + \int_{t_1}^{t_0+T} E_r dt = 0 \tag{14}$$

For the half-wave circuit

$$\left.\begin{aligned} E_f &= V_m \sin \omega t - I_f(R_L + r + R_f) \\ E_r &= V_m \sin \omega t - I_r(R_L + r + R_r) \\ E_r &\approx V_m \sin \omega t - V_g \end{aligned}\right\} \tag{15}$$

where R_L, r, R_f, and R_r are the load, reactor winding, rectifier forward, and rectifier reverse resistances respectively. (R_r is not assumed constant.) I_f and I_r denote the forward and reverse instantaneous values of mesh current, and V_g is the instantaneous reverse rectifier voltage. From equations 14 and 15 there obtains the result

Figure 10. Rectifier reverse a-c volt-ampere characteristic (10-disk selenium rectifier)

$$V_z = I_f(R_L + r + R_f)$$

where V_z and I_f are average values taken over a complete period, t_0 to t_0+T. If the assumption of equal periods of forward and reverse rectifier current flow is made, then

$$V_{zh} = 2I_f(R_L + r + R_f) \tag{16}$$

V_{zh} is the half-period average or d-c value of reverse rectifier voltage over the interval of reverse current flow. The periods of forward and reverse current flow are nearly equal in actual circuits, except possibly in the region of minimum load current where rectifier leakage effects are unimportant. This is not the same as assuming zero current overshoot, and applies even when the overshoot is appreciable. Following the same line of reasoning, for the full-wave and doubler circuits, one correspondingly obtains for full-wave

$$V_{zh} = 2I_f(2R_L + r + R_f) \tag{17}$$

for doubler

$$V_{zh} = 2I_f(r + R_f) \tag{18}$$

where I_f is the average forward current per mesh. From equations 16 to 18 it is seen that the leakage effects are smallest in the doubler, intermediate in the half-wave, and largest in the full-wave circuits.

The determination of rectifier reverse current flow requires a knowledge of the wave form of V_z. For the purpose of evaluating the contribution of reverse current (a small effect) to the average load value, V_z may be assumed half sinusoidal in shape. The corresponding half-period average current I_{rh} is obtained from the

Figure 11. Equivalent circuit of core demagnetization effect caused by rectifier leakage current

a-c reverse characteristic as shown in Figure 10. The average load current per mesh then is given by

$$I_L = I_f \pm I_r, \text{ where } I_r = \frac{1}{2} I_{rh} \tag{19}$$

The minus sign applies to the half and full-wave circuits, and the plus sign to the doubler circuit.

The determination of rectifier leakage demagnetization effect requires a somewhat different approach. Integration of the reactor inductive voltage drop over the interval of reverse current flow yields the relation

$$2\frac{N}{T}(\Phi_a - \Phi_c') = E_{rh} = V_k - V_{zh} \tag{20}$$

where

$$V_k = \frac{V_m}{\pi}(\cos \omega t_0 - \cos \omega t_1) + \begin{Bmatrix} 0 \\ -1 \\ +1 \end{Bmatrix} 2I_f R_L$$

E_{rh} is the d-c value over the interval t_1 to t_0+T. The $(0, -1, +1)$ refer to the half-wave, full-wave, and doubler circuits respectively. Equal intervals of forward and reverse rectifier current flow are assumed. $(\Phi_c - \Phi_c')$ is the core demagnetization equivalent of rectifier leakage current. If it is assumed that the effect on average load current is contained completely in the reduction of core premagnetization, then the same effect results from applying two series d-c batteries, having voltages V_{zh} and V_k, across the load winding of the reactor for a half-period $1/2T$ as results under actual operating conditions. The equivalent circuit is shown in Figure 11. The constant reverse rectifier current I_{Ld} required to produce the fixed voltage V_{zh} is obtained directly from the rectifier d-c reverse volt-ampere characteristic (not shown). When referred to the control circuit

$$I_{cd} = \frac{N}{N_c} I_{Ld} \tag{21}$$

I_{cd} is the equivalent d-c control current which must be added to the original value (without leakage) in order to maintain the same average value of load current. Therefore, if the transfer curve for the basic half-wave circuit is given, the curves for all three circuits, with rectifier leakage, can be obtained.

The plotted points shown by crosses in Figures 8 and 9, computed by correcting the corresponding number 2 curves for rectifier leakage by the preceding method, show reasonably good agreement with the measured transfer curves with selenium rectifiers. Measured transfer curves for the three types of circuits with orthonik and hypersil reactors are shown respectively in Figures 12 and 13. Selenium rectifiers are used throughout. Demagnetization effect was found to be negligible in the particular doubler circuits. It was assumed that the doubler curves were free from leakage effects, and, therefore, essentially identical with the curves of the corresponding basic half-wave circuits (without leakage). Corrections then were computed for the half and full-wave circuits and these points are shown in the figures. The method proposed for evaluating leakage effects, although not analytically exact, has a firm theoretical basis and yields results which are useful and accurate enough to give a good appreciation of these effects.

Control-Circuit Resistance Effect

When the control circuit contains finite resistance and no external choke, transformer action between load and control meshes results in the half-wave circuit, and coupling between the two load meshes results in the full-wave and

Figure 12. Comparison of transfer curves (orthonik cores and constrained magnetization): A. Doubler; B. Half-wave; C. Full-wave

doubler circuits. The two effects are basically different and require separate consideration.

Half-Wave Circuit

The control mesh voltage equation becomes

$$V_{D-C}=r_e i_c+N_c A\frac{dB}{dt} \tag{22}$$

If the idealized approach is followed as in the basic half-wave circuit, then from equations 2 and 22, the presaturation load current is given by

$$i=\frac{V_m}{R_T+r_e'}\sin\omega t \tag{23}$$

and

$$V_m'\sin\omega t=NA\frac{dB}{dt} \tag{24}$$

where

$$r_e'=\frac{N^2}{N_c^2}r_c,\quad V_m'=\frac{r_c'}{R_T+r_e'}V_m,\quad B_m'=\frac{V_m'}{\omega NA}$$

The flux builds up as in the constrained case but with reduced voltage V_m'. The saturation angle is found from equation 5 by substituting B_m' for B_m. The saturation angle is seen to be increased over the constrained case. The presaturation average load current is found from equation 23 to be

$$I_{pr}=I_s\frac{R_T}{r_c'}\left(\frac{B_s-B_c}{2B_m}\right) \tag{25}$$

After saturation, the current flows as in the constrained case, and the average value obtained from B_m' and equation 6 reduces to

$$I_{po}=I-I_s\frac{R_T}{r_c'}\left(\frac{B_s-B_c}{2B_m}\right) \tag{26}$$

The total average load current is

$$I_T=I_{pr}+I_{po}=I \tag{27}$$

This rather surprising result states that, under idealized conditions, the value of average load current corresponding to a particular presaturation flux density B_c is independent of control circuit resistance. The increase due to presaturation current is exactly compensated by the decrease in postsaturation current. The value of d-c control circuit current required to produce a given B_c does, however, depend upon control circuit resistance.

During the presaturation period, alternating current flows in the control circuit by transformer action; after saturation and until time $(1/2)T$, $dB/dt=0$, and the control current remains constant at its d-c value. The average control current over the positive half-cycle is

$$I_c=\frac{V_{D-C}}{r_c}-I_{MC} \tag{28}$$

where

$$I_{MC}=2\frac{N}{N_c}I_{pr}=2\frac{N_c}{N}\frac{R_T}{r_c}(I_s-I) \tag{29}$$

The average value of control current over an entire period must equal the d-c impressed value. Therefore, the d-c value of control current during the negative half-cycle is

$$I_{c-}=-\frac{V_{D-C}}{r_c}+I_{MC} \tag{30}$$

The presaturation flux density is primarily a function of the descending branch of the hysteresis loop[4] and, in the ideal sense, depends upon the average field intensity of the core during unsaturation. Consequently, the term I_{MC} acts as a magnetizing component in the control circuit. Therefore, if the d-c control current were decreased by an amount I_{MC}, the same premagnetization flux (and average load current) would result as in the constrained case corresponding to the original value. Although the preceding analysis is based upon idealized considerations, the results can be applied to nonideal cases. I_{MC} is interpreted as a correction which is applied to the constrained transfer curve obtained by previously described methods. It is shown readily that the average reverse rectifier voltage is the same as in the constrained case, and the effect of rectifier leakage may be assumed the same as in this case.

Measured transfer curves for the orthonik amplifiers, for several values of control-circuit resistance, are given in Figure 14. Computed points show good agreement with the measured curves to the right of the minimum point in each case. To the left of the minimum point the idealized considerations, which neglect magnetizing currents, do not apply. However, it is possible to estimate the transfer curve for the case of finite control resistance by correcting the constrained curve down to the point of intersection with the left-hand branch of the constrained curve. To the left the constrained curve may be used.

Full-Wave and Doubler Circuits

The full-wave and doubler circuits with finite control-circuit resistance are not amenable to simple analytic methods; only the limiting cases of constrained and natural (zero control-circuit resistance and no external choke) magnetization are considered. The basic mesh voltage equations for Natural Magnetization are

$$\left.\begin{aligned} V_m \sin \omega t &= R_1 i_1 \pm R_L i_2 + N\frac{d\Phi_1}{dt} \\ -V_m \sin \omega t &= \pm R_L i_1 + R_2 i_2 + N\frac{d\Phi_2}{dt} \\ 0 &= \frac{d\Phi_1}{dt} + \frac{d\Phi_2}{dt} \end{aligned}\right\} \tag{31}$$

By substitution, the equations for meshes 1 and 2 may be put in the form

$$\left.\begin{aligned} V_m \sin \omega t &= R_1' i_1 + N\frac{d\Phi_1}{dt} \\ -V_m \sin \omega t &= R_2' i_2 + N\frac{d\Phi_2}{dt} \end{aligned}\right\} \tag{32}$$

Figure 16. Transfer curves with constrained and natural magnetization (orthonik full-wave circuit)

1. Constrained magnetization with *5R4YG* rectifiers; 2. Natural magnetization with *5R4YG* rectifiers; 3. Constrained magnetization with selenium rectifiers; 4. Natural magnetization with selenium rectifiers

where

$$R_1' = \frac{R_1 R_2 - R_L^2}{R_2 \pm R_L}, \quad R_2' = \frac{R_1 R_2 - R_L^2}{R_1 + R_L}$$

The $\pm$ sign applies for the full-wave and doubler circuits, respectively. R_1' and R_2' assume different values depending upon the direction of current flow in the individual meshes.[4] If idealized operation is approached, then the presaturation mesh current is negligible, and the flux build-up in one mesh (accompanied by flux decay in the adjoining mesh) proceeds as in the Constrained Magnetization case. For ideal operation (rectangular hysteresis loop materials) the Natural Magnetization and Constrained Magnetization cases are identical. It is therefore evident that differences in performance which occur are due essentially to deviation of the magnetic core hysteresis loop from the ideal shape. A very simple nonideal shape will be considered.

The characteristic curve will be assumed to have a large linear slope in the unsaturated region, and zero slope in regions of positive and negative saturation. In the absence of alternating voltage, a d-c control current I_c would produce a value of flux Φ_c in each core, as shown in Figure 15(B). The solid circle and cross (1 and 2 in the figure) denote initial values of flux in reactors number 1 and 2. If the alternating voltage now is applied, the flux in reactor number 1 builds up to saturation (Φ_s) sinusoidally, and, from equation 31, the flux in reactor number 2 decreases by an equal amount. As core number 1 unsaturates (starting at time 1/2T) Φ_1 decreases from 1′ to 1, and Φ_2 increases from 2′ to 2. It was stated before that core number 2 should saturate as number 1 unsaturates, but the above description has left the second reactor unsaturated at the time at which the first reactor has returned to its premagnetization flux value. The circuit must finally settle down to steady-state operation at a reduced effective premagnetization flux.

The flux conditions necessary to produce steady-state operation, with initial cyclic flux Φ_c, are shown in Figure 15(C). At the start of a positive half-cycle of supply voltage $\Phi_1 = \Phi_c$ as before, but $\Phi_2 = \Phi_s$. Steady-state operation between the limits Φ_c and Φ_s now obtains, and the load current is the same as in the Constrained Magnetization case with the same flux variation. In order to achieve this initial flux situation, the d-c control current must be increased by the amount required to place point 2 initially at saturation; that is

$$I_{BX} = \frac{1}{2}(I_{SA} - I_c) \tag{33}$$

The maximum value of I_{BX} occurs at minimum load current, or at $I_c = -I_{SA}$. Therefore,

$$I_{BX(\max)} = I_{SA} \tag{34}$$

The results of the preceding analysis may be used to estimate the deviation between Natural Magnetization and Constrained Magnetization transfer curves. An approximate value of I_{SA} can be obtained for nonideal materials by extending a line, drawn tangent to the upper branch of the hysteresis loop at the axis of the field intensity, to saturation flux value. The deviation of the line at saturation from the ideal rectangular shape loop specifies an approximately equivalent I_{SA}. For orthonik and hypersil the values, referred to the control winding, are 11.6 and 29.8 milliamperes, respectively. Reference to measured transfer curves in Figures 16 and 17, for full-wave amplifiers using the two materials, reveals the maximum deviation between the Natural Magnetization and Constrained Magnetization curves to be about 11 and 28 milliamperes for orthonik and hypersil, respectively.

Average values of reverse rectifier voltage for corresponding Natural Magnetization and Constrained Magnetization circuits are equal, and it may be assumed

Figure 17 (right). Transfer curves with constrained and natural magnetization (hypersil full-wave circuit

that the effect of rectifier leakage is the same in both cases.

Conclusions

A direct mathematical approach to the determination of magnetic amplifier performance invariably leads to abridgment or omission of very significant characteristics of the circuit elements. By considering the circuit operation on a regional basis, these characteristics may be more fully considered without complicating the problem to the point of insolvability. Idealized methods, when properly interpreted, may be extended to nonideal situations with useful results. In particular, it is possible to estimate the effect of finite control-circuit resistance in the half-wave circuit, the corresponding effect of mesh coupling through the control circuit in the full-wave and doubler circuits, and rectifier leakage effects in all three circuits by application of these methods.

Appendix I. Sample Calculation of Transfer Curve for a Basic Half-Wave Circuit

Amplifier Data

Hypersil toroidal wound core, 0.005-inch strip

$l_m = 11.5$ inches

$A = 1.64$ square inches

$N = 276$

$N_c = 100$

$R_L = 30$ ohms

$r = 1.40$ ohms

$V = 100$ volts rms, 60 cycles per second

$B_s = 120$ kilolines per square inch

$$B_m = \frac{V_m}{\omega NA} = \frac{\sqrt{2}\times 100\times 10^8}{120\pi\times 276\times 1.64} = 82.8 \text{ kilolines per square inch}$$

$R_L + r = 30 + 1.40 = 31.4$ ohms

From Figure 3 and the appropriate load line

$I_s = 1.23$ amperes

and from Figure 4

$R_f = 5.5$ ohms

In the region of large core presaturation, equation 6 applies

$$I = I_s\left[1-\left(\frac{B_s - B_c}{2B_m}\right)\right]$$

$$I = 1.23\left[1-\left(\frac{120 - B_c}{165.6}\right)\right]$$

Also

$$I_c = \frac{l_m H_c}{N_c}$$

For various values of B_c, values obtained for I_c and I are given in Table I.

In the region of small load current the maximum symmetrical flux variation falls above the knee of the magnetization curve; equation 10 applies here. Corresponding to $B_m = 82.8$ kilolines per square inch, there is observed

$H_m = 2.58$ ampere turns per inch

$D_m = 1.55$ ampere turns per inch

From equation 10

$$H_L = H_m + D_m S_1(\sigma)$$

$$= 2.58 + 1.55 S_1(\sigma)$$

Table II gives values of the transfer curve for a basic half-wave circuit using the equations developed in Appendix I.

The plotted results are shown in Figure 5. The linear region of the transfer curve is approximated by a straight line drawn from I_{min} tangent to the computed upper branch as previously explained.

Appendix II. Sample Calculation of Rectifier Leakage Effect

Amplifier Data

Full-Wave Circuit, Orthonik Toroidal Wound Core, 0.001-inch strip

$l_m = 7.7$ inches

$A = 1.0$ square inch

$N = 400$

$N_c = 100$

$R_L = 160$ ohms

$r = 14.4$ ohms

$V = 60$ volts rms, 60 cycles per second

$R_f = 28.6$ ohms

$R_T = R_L + r + R_f = 203$ ohms

From equation 17

$$V_{sh} = 2(R_L + R_T)I_f$$

$$= 2(160 + 203)I_f$$

$$= 726 I_f$$

The control current is corrected by adding the component I_{cd}

$$I_c' = I_c + I_{cd}$$

where

$$I_{cd} = \frac{N}{N_c} I_{Ld} = 4 I_{Ld}$$

The reverse current I_r is not considered.

To avoid simultaneous comparison of several computed results, the measured constrained transfer curve for the doubler circuit is assumed to be identical with ideal curve of the basic half-wave circuit. The full-wave transfer curve then is obtained by correcting the doubler curve for leakage. (It is readily demonstrated that this particular doubler circuit is essentially free of rectifier leakage effect.)

Table III gives values for the full-wave transfer curve, taking the rectifier leakage effect into account.

The computed values for the full-wave circuit are plotted for comparison with the measured curve in Figure 12.

Transient Analysis of a Voltage-Regulated Aircraft D-C System

DONALD G. SCORGIE
ASSOCIATE AIEE

IN PRESENT-DAY aircraft d-c systems some form of automatic voltage regulator is always necessary. Most commonly used is the carbon-pile type which has been analyzed in detail.[1,2] This paper includes a study of the transient characteristics of a d-c generator and of the combined regulator-generator system. Two objectives are in mind, the first to express qualitatively the stability and speed-of-recovery characteristics of the system, and the second to express exactly the terminal voltage transient upon removal of load as a function of the parameters of the regulator and generator. The latter problem is of interest to designers of circuit breaker equipment.

Basic principles of the theory of servomechanisms and feedback amplifiers have been utilized in this study. The great usefulness of servomechanism theory is due in part to the fact that a complex system may be broken into smaller components, and the characteristics of each analyzed and measured separately. This advantage is lost in analyzing by the usual approach[3] a system containing a carbon pile voltage regulator. The d-c reference voltage for the system is furnished by a critical balance of forces within the carbon pile regulator. If one allows this reference voltage to enter the study, the several transfer functions and the feedback loop within the regulator must be analyzed. This analysis is quite difficult, and cannot be checked empirically. Therefore, in this paper, the entire regulator is treated as a single component in a closed control loop.

The resulting analysis is not without disadvantages. The disadvantages, however, lie in the need for initial clarity and understanding rather than in the use of the results. In this paper the inputs to the generator-regulator system are considered to be perfect equivalent-voltage generators introduced in the generator armature and field circuits because of external disturbances such as the removal of generator load. The variable, $E_o(t)$, corresponding to servomechanism output is defined as the contribution to the generator terminal voltage due to field resistance changes and other inputs to the field. To conform with standard terminology, this quantity is called the output. However, it is the algebraic sum of this output and the armature input which actually appears at the generator terminals and directly affects the voltage regulator. This sum is the error, $\mathcal{E}_1(t)$, which is the variable to be controlled, and it becomes convenient later to define and utilize the error transfer function.

Both the generator and the regulator are highly nonlinear components, and the latter introduces the feature of a purposely variable parameter, namely carbon pile resistance. However, linearizing assumptions have been made, and consequently it has been possible to derive the transfer functions of both regulator and generator. The utility of these approximations is illustrated by the close agreement between calculated and measured terminal voltage transients which are presented in this paper.

By means of the frequency spectrum analysis technique discussed briefly in a later section, qualitative predictions of system performance can be made from an inspection of the transfer function of the control loop. The loop transfer function is determined easily from the derived transfer functions of the individual components. In turn, the effect of a single parameter change upon a component of the loop can be easily seen. The method, therefore, provides a swift, convenient tool with which to investigate methods of improving voltage regulation.

The Regulator Transfer Function

The system which will be analyzed consists of a shunt wound d-c generator and a carbon pile voltage regulator connected as shown in Figure 1. Each of these components is highly nonlinear. It was pointed out in an earlier paper[1] that the carbon pile regulator remained linear for small changes from some arbitrary reference condition in the operating range. The transfer function of a stable linear component was defined there as the complex ratio (a function of frequency) of a sinusoidal output variation to the sinusoidal input which produced it. (An alternative definition is the ratio of the Laplace transforms of output to input, the input being an arbitrary function of time.) In the case of the carbon pile regulator, the input quantity is a voltage disturbance at the operating coil terminals, and the output is a variation of the resistance of the carbon pile. Each is measured with respect to some arbitrary

Figure 1. Regulated aircraft d-c generator

Paper 50-208, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 5, 1950; made available for printing August 16, 1950.

DONALD G. SCORGIE is with the Naval Research Laboratory, Washington, D. C.

The author wishes to express his appreciation to N. W. Matthews, R. L. Mills, and D. H. Schaefer for their valuable suggestions and criticisms.

reference point taken as zero in the operating range. The transfer function of the regulator was derived as

$$T_r = \frac{UP}{R_cK - \omega^2 R_c M + j\omega(LK + U^2 - \omega^2 LM)} \quad (1)$$

where

U = coupling coefficient equal to the rate of change of magnet force per change of operating coil current
P = carbon pile resistance change per-unit change of carbon pile length
R_c = resistance of the operating coil circuit
K = difference in rates of change of force with deflection between the magnet curve and the carbon pile curve
M = effective mass of the armature
L = incremental inductance of the operating coil

The transfer function given in equation 1 is unwieldy, but can be simplified for use in analyzing the system under study. The simplification relies upon the fact that, for frequencies above a certain low band, the characteristics of the regulator contribute very little to the system performance. If the assumption is made that the top of the band is considerably below the frequency for which the regulator phase shift is 90 degrees (that is, $\omega^2 \ll K/M$) then equation 1 can be approximated by

$$T_r = K_r\left(\frac{\alpha_r}{j\omega + \alpha_r}\right) \quad (2)$$

where

$$K_r = \frac{UP}{KR_c}$$

and

$$\alpha_r = \frac{R_cK}{U^2 + KL}$$

The Generator Transfer Function with No Load

The generator no-load transfer function will be first defined assuming that the output of the regulator is the sole input to the generator. That is to say—the generator will be disturbed by a variation, $R(t)$, of shunt field resistance.

Suppose for the purpose of this derivation that the generator is operating in its normal no-load condition, but with no regulator. If the field resistance is suddenly changed by a small step, $\Delta R = (R_2 - R_1)$, the resulting terminal voltage transient is $E_o(t)$. The generator transfer function T_g', is the ratio of the Laplace transforms of these time functions,*

$$T_g' = \frac{E_o}{R}(s)$$

In order to derive the transfer function, we assume that no-load saturation curve of the generator is a straight line with slope K_s at the operating point. The following differential equation would be exact throughout the transient

$$E_o(t) = L_f\frac{di(t)}{dt} + R_s i(t) + I_1\Delta R \quad (3)$$

where

i = change of field current from the initial value
I_1 = initial shunt field current
L_f = incremental self inductance of the field circuit

But the saturation curve was assumed to be

$$E_1(t) = K_1 + K_s I_f(t) \quad (4)$$

so that

$$E_o(t) = K_s i(t) \quad (5)$$

From equations 3 and 5

$$-I_1\Delta R = \frac{L_f}{K_s}\frac{dE_o(t)}{dt} + \frac{E_o(t)}{K_s}(R_s - K_s) \quad (6)$$

* The same symbols will be used for time functions and their Laplace transforms with the appropriate variable (t or s) indicated at all times.

the Laplace transform of equation 6 is

$$-K_s\frac{I_1\Delta R}{s} = E_o(s)[sL_f + R_s - K_s] \quad (7)$$

or

$$E_o(s) = -\frac{\Delta R}{s}\left[\left(\frac{K_sI_1}{R_s - K_s}\right)\left(\frac{\frac{R_s - K_s}{L_f}}{s + \frac{R_s - K_s}{L_f}}\right)\right] \quad (8)$$

If ΔR is very small relative to $R_1 - K_s$, equation 8 becomes

$$E_o(s) = -\frac{\Delta R}{s}\left[\left(\frac{K_sI_1}{R_1 - K_s}\right)\left(\frac{\frac{R_1 - K_s}{L_f}}{s + \frac{(R_1 - K_s)}{L_f}}\right)\right] \quad (9)$$

This is the product of a driving function, $\Delta R/s$ and the transfer function of the generator, which can be written

$$T_g' = -K_g'\left(\frac{\alpha_g}{s + \alpha_g}\right) \quad (10)$$

where

$$\alpha_g = \frac{R_1 - K_s}{L_f}$$

and

$$K_g' = \frac{K_sI_1}{R_1 - K_s}$$

The transfer function given in equation 10 is, of course, independent of the input function provided it remains small.

It will be more convenient to consider the input to the generator as a voltage instead of a resistance. Rearranging equation 3, assuming

$\Delta R \ll R_1$

Figure 2. Schematic diagram of regulator test circuit

$$E_s(t) - I_1 \Delta R = L_f \frac{di(t)}{dt} + R_f i(t) \tag{3}$$

Then evidently $-I_1 \Delta R$ is equivalent to a voltage, $\mathcal{E}'$, impressed upon the field circuit of the generator. The second form of the transfer function is given by

$$T_g = \frac{E_o}{\mathcal{E}'}(s) = +K_g\left(\frac{\alpha_g}{s+\alpha_g}\right) \tag{11}$$

where

$$K_g = \frac{K_s}{R_1 - K_s}$$

E_o also affects the shunt field directly. This constitutes a minor feedback loop within the generator, but in no way invalidates the over-all transfer function.

Measurement of Generator Transfer Function

If the generator were truly a linear device, the measurement of its transfer function would be quite simple. It would only be necessary to introduce a step function change of resistance into the field circuit and measure the time constant of the resulting exponential rise of terminal voltage. Unfortunately, even small hysteresis in the magnetic circuit of the generator introduces large errors in the results obtained by such a test. In its place a method has been devised for introducing a sinusoidally varying resistance into the generator field circuit and for measuring the sinusoidal terminal voltage response. In a previous paper[1] an electronic circuit was described for measuring the transfer function of a carbon pile regulator. This circuit is reproduced in Figure 2. The same circuit may be utilized in the analysis here, but in addition, a special carbon pile regulator is required. A regulator was obtained in which the armature compresses two carbon piles instead of one. The two piles are electrically isolated from each other, and one is used in the electronic circuit as shown in Figure 2. When a sinusoidal signal is introduced into the electronic circuit both piles respond. The second may be used to introduce the sinusoidal resistance variation into the field of the d-c generator, and the transfer function is thus obtained easily by measuring the relative magnitude and phase of the voltages at the generator terminals and the grid of the first *6SL7* triode, Figure 2.

A typical result is shown in Figure 3. The transfer function is measured with constant generator output variation at all frequencies in order to assure that the iron in the magnetic circuit is operating around the same minor hysteresis loop for all measurements. The second curve, which is offered for comparison, is the transfer function of a simple time lag with inverse time constant $\alpha_g = 5.7$ and amplification $K_g = 1.5$.

Figure 3. Generator transfer function

Analytical System Response

The system under study can be represented schematically by the block diagram of Figure 4. E_i and E_i' are voltages introduced into the generator armature and field circuit, respectively, due to some disturbance such as the removal of load. The other symbols are as given previously with the exception of T_f which is the transfer function used to convert resistance change into an equivalent voltage in the field circuit. By definition

$$\mathcal{E}_1(t) = E_i(t) + E_o(t) \tag{12}$$

and

$$\mathcal{E}_2(t) = E_i'(t) + \mathcal{E}'(t) \tag{13}$$

Of the seven variables indicated in Figure 4, only $\mathcal{E}_1(t)$ is directly measurable while the system is operating. $\mathcal{E}_1(t)$ is the total change of terminal voltage from the initial operating point, so it is this quantity with which we are chiefly concerned in voltage regulator problems. The Laplace transforms of equations 12 and 13 can be written

$$\mathcal{E}_1(s) = E_i(s) + E_o(s) \tag{14}$$

and

$$\mathcal{E}_2(s) = E_i'(s) + \mathcal{E}'(s) \tag{15}$$

Suppose for the moment that $E'_i = 0$. We get the additional equation

$$E_o(s) = \mathcal{E}_i(s).T_r.T_g.T_f \tag{16}$$

or

$$T_r.T_g.T_f = \frac{E_o}{\mathcal{E}_i}(s) \tag{17}$$

where $E_o/\mathcal{E}_1(s)$ is known as the loop transfer function. From equations 14, 16, and 17 we get the contribution to the terminal voltage variation due to E_i as the inverse transform of

$$E_i(s)\left(\frac{1}{1-\frac{E_o}{\mathcal{E}_i}(s)}\right)$$

Now suppose that $E_i = 0$ and E_i' is not zero. We know that

$$E_o(s) = T_g.\mathcal{E}_2(s) \tag{18}$$

$$\mathcal{E}'(s) = \mathcal{E}_i.T_r.T_f \tag{19}$$

From equations 14, 15, 18, and 19 we find that the contribution to the terminal voltage transient due to E_i' is given by the inverse transform of

$$E_i'(s)\left(\frac{T_g}{1-\frac{E_o}{\mathcal{E}_i}(s)}\right)$$

The transform of the total terminal voltage transient is

$$\mathcal{E}_1(s) = E_i'(s)\left(\frac{T_g}{1-\frac{E_o}{\mathcal{E}_i}(s)}\right) + E_i(s)\left(\frac{1}{1-\frac{E_o}{\mathcal{E}_i}(s)}\right) \tag{20}$$

Input Due to Removal of Generator Load

It is desirable to check the validity of equation 20 by both measuring and cal-

Figure 4. Block diagram of regulator-generator system

Figure 5. Voltages equivalent to removal of load

culating a transient response to a known input. Unfortunately, the input disturbances which can be applied to a system are not readily controlled independent variables. The simplest common input is the removal of load from the generator. If a good circuit breaker is used, the load drops linearly to zero. Nevertheless the equivalent input is complicated and consists of several superimposed voltages as follows:

1. The change of IR_a voltage drop which is linear with time while current is decreasing (R_a = armature resistance).

2. A step function voltage which is introduced in the armature circuit as a result of armature circuit self-inductance and mutual inductance with the shunt field. An equal but opposite step function occurs as the load current reaches zero.

3. A voltage due to the change of direct armature reaction and cross magnetizing of the pole face. This demagnetizing voltage is assumed to change linearly with load current and constitutes an input disturbance to the armature circuit.

4. A step function voltage is introduced into the field circuit due to the mutual inductance between the armature and field windings. When the load current reaches zero an equal but opposite step function results.

These voltages can be considered as perfect generators in series with the armature and shunt field circuits, (1), (2), and (3) being inputs corresponding to E_t of equation 20 and (4) corresponding to E_t'. In Figure 5, these are represented by G_a and G_f respectively. Figure 5 also indicates the quantities E_t and E_t' which correspond to those of Figure 4. By definition the voltage of G_f is E_t', but we must assume that the armature inductance and resistance are negligibly small with respect to the shunt field inductance and resistance before it is obvious that the voltage of G_a is E_t. In Appendix I a discussion is presented showing that the input voltages (3) and (4) above lead to equal and opposite terminal voltage responses and hence will be neglected.

Figure 6. System response to removal of full load

Calculated and Measured Transients Compared

It was pointed out previously that the generator is nonlinear and that both amplification and time constant depend upon the incremental permeability of the magnetic circuit, hence upon the magnitude of the output signal. The transfer function of the generator is measured for a number of signal amplitudes and at a number of initial operating points it is seen that K_g and α_g vary between upper and lower limits. For an arbitrarily chosen generator which was tested, K_g varied between 1.50 and 2.00 and α_g varied between 4 and 9. The mean values then were $K_g = 1.75$ and $\alpha_g = 6.5$. The same condition existed when measuring the regulator transfer function, and an average yielded $K_r = 15$ and $\alpha_r = 65$.

Using these four constants, calculations have been made of the terminal voltage response to the removal of full load from the generator. It was assumed that a 75-ampere load was reduced linearly to zero in 0.002 second. The mean inductance and resistance of the generator armature were measured as 0.000373 henry and 0.1 ohm respectively. Using the inputs (1) and (2) discussed previously, and taking the inverse Laplace transform of equation 20 for both cases, the following two time functions are determined:

$$f_1(t) = \left[-L_a + M\left(\frac{M+L_a}{M+L_f}\right)\right]\frac{di_a}{dt} \times$$

$$\left[\frac{1}{1+K_rK_g} - K_rK_g \times \right.$$

$$\left. \frac{\alpha_r\alpha_g}{\sqrt{(1+K_rK_g)\alpha_r\alpha_g(1+K_rK_g) - \left(\frac{\alpha_r+\alpha_g}{2}\right)^2}} \times e^{-\alpha t}\sin(\beta t+\psi)\right] \quad (21)$$

where

M = mutual inductance between the field and armature circuits, where the armature circuit is taken to include compensating and commutating windings

L_a = armature inductance

i_a = load current

$$\alpha = \frac{\alpha_r+\alpha_g}{2}$$

$$\beta = \sqrt{\alpha_r\alpha_g(1+K_rK_g) - \left(\frac{\alpha_r+\alpha_g}{2}\right)^2}$$

$$\psi = \tan^{-1}\left(\frac{\beta}{\alpha}\right)$$

and

$$f_2(t) = -R_a\frac{di_a}{dt}\left\{\frac{K_rK_g(\alpha_r\alpha_g)}{\alpha_r\alpha_g(1+K_rK_g)^2} + \frac{t}{1+K_rK_g} - \frac{K_rK_g}{\beta(1+K_rK_g)}e^{-\alpha t}\sin(\beta t+2\psi)\right\} \quad (22)$$

The sum of two time functions is easily plotted. At time $t = 0.002$ when the load current reaches zero, the same quantity but with opposite sign is again introduced. The total value is shown plotted in Figure 6, and is seen to be substantially in agreement with the measured transient.

Frequency Spectrum Analysis

The function $\varepsilon_t/E_t(s)$ is called the error transfer function, and from it predictions

Figure 7. Loci of constant magnitude of error transfer function on loop transfer function complex plane

of system performance can be made qualitatively without laborious calculations. The absolute magnitude of the ideal error transfer function would of course equal zero for all frequencies, but this is never even approximately realized in practice. Typically, the magnitude of the error transfer function is very small at zero frequency, then rises to a resonance peak. At higher frequencies it then drops asymptotically to 1.0. In general, the error response to a transient disturbance will take the form of a damped sinusoid of frequency near that of the error transfer function resonance peak. The oscillation will be damped to a lesser degree the larger the magnitude of the resonance peak, so every effort is made to keep this peak as small as possible. In addition, however, the error transient depends upon the predominant frequencies in the input disturbance. The common inputs such as step functions and ramp functions have frequency components which drop off at least at $1/\omega$ or faster. It is therefore better in general to have a resonance peak occur at higher frequencies. Special considerations must be taken into account individually. For instance, mechanical vibration of frequency near the resonance peak must be avoided.

The error transfer function must be expressed in terms of the loop transfer function to be of great use. This can be done if E_t' can be made zero, see equation 20. However, E_t' and E_t are not truly independent of each other because of the mutual coupling between the armature and field circuits. We have previously shown a specific instance where the response due to E_t' was cancelled by the response due to that portion of E_t arising from the demagnetizing effect of armature current. These two transient responses virtually cancel each other even when $I_a(t)$ has a more general form, since equation 20 will always have a multiplying term $[s/(s+\alpha_p)-1]$ which is zero for all but extremely low frequencies. The steady-state values do not cancel each other of course. If E_t includes only those inputs due to $i_a r_a$ drops and self induction in the armature circuit, it is then seen that $\mathcal{E}_1/E_t(s)$ can be expressed in terms of the loop transfer function alone. The loop transfer function in turn is determined easily from the characteristics of the individual components of the control loop. Once the relationship between loop and error transfer functions is established it is no longer necessary to plot the error transfer function in order to analyze the system.

We therefore plot the loop transfer function on the complex plane which indicates its magnitude and phase shift at each frequency, Figure 9. Using equation 20, a magnitude and phase shift, Figures 7 and 8 respectively, of the error transfer function can be determined corresponding to every point on the loop transfer function complex plane. Typical constant magnitude loci are shown to be circles concentric about the $1+j0$ point. The radii of these circles are given by

$$r = \frac{1}{\left|\frac{\mathcal{E}_1}{E_t}\right|}$$

Typical constant phase shift loci are shown to be radii emanating from the $1+j0$ point. If Nyquist's[4] stability criterion is satisfied then the resonance peak of the error transfer function is determined solely by the point at which the loop transfer function approaches closest to the $1+j0$ point. Figure 9 shows the loop transfer function of two generator-regulator systems. These functions were calculated using equation 16 and experimental values of T_r and T_g. System number 1 in the figure is the generator-regulator system which was used for the preceding transient analysis. The frequency for which the curve most nearly approaches the critical point is 19 cycles. Noting the co-ordinates of this point and referring to Figure 7 this corresponds to an error transfer function magnitude of slightly less than 2.0. The transient response shown in Figure 6 is a damped sinusoid whose period is approximately 0.058 second. The reciprocal of the period is a frequency of about 17 cycles per second as would be expected. In Figure 9 and Figure 10 this system is compared with another which employed the same regulator with a different generator, system number 2. In system number 2 the peak magnitude of the error transfer

Figure 9. Loop transfer functions of generator-regulator systems

Figure 8 (left). Loci of constant phase of error transfer function on loop transfer function plane

Figure 10 (right). Terminal voltage transients due to removal of load

function is considerably larger (2.87), but it occurs at a higher frequency and therefore is not excited to such a large degree by the input disturbance. The frequency at which the loop transfer function is closest to the $1+j0$ is about 34 cycles, whereas the corresponding transient response is a damped sinusoid of approximately 31 cycles per second.

Summary

The system consisting of a single generator and a carbon pile voltage regulator is a closed-loop regulating system of the proportional type. As such, its stability and dynamic characteristics can be analyzed by the standard theory of servomechanisms. It is, however, necessary to define the variable quantities very carefully as they are not easily recognizable or measurable. For this system it is convenient to utilize the concept of an error transfer function (defined in this paper) rather than to use the system transfer function common in servomechanism literature. When this is done the criteria for frequency spectrum analysis are altered somewhat, as discussed before.

The purpose of the foregoing analysis has been to simplify the problem of improving an existing regulator-generator system. A complete loop transfer function can be written in terms of the regulator and generator parameters. From this it can be seen by inspection whether a given system will be stable. For stable systems the effect of changing parameters can easily be determined by examining equations 2, 10, 21, and 22.

It is clear that the regulator characteristics alone do not determine the stability of the system. The generator and regulator characteristics must be considered together instead of separately. When the same regulator is used with two different generators, one system may be stable while the other is not. This can be due to the difference of the generator characteristics alone. However, it may be due to the fact that, in order to obtain the desired direct voltage, it has been necessary to operate the regulator at a different starting point. Hence, with a second generator the parameters of the regulator itself may have been effectively changed. Therefore, even though the d-c terminal voltage has been ignored in the foregoing analysis, it is important that it be considered in relation to the restrictions which it places upon a free choice of regulator and generator parameters.

The generator transfer function derived in this paper was for no load only. However, the extension to the case of load is possible by means of standard circuit analysis.

Appendix. Neglected Input Disturbances

In the calculation of transient response to the removal of full generator load two voltage inputs were neglected. These were (3) and (4) under the general discussion of inputs. The first of these is a ramp function, $E_a = K't$, impressed upon the armature circuit, and the time response is the corresponding inverse Laplace transform of equation 20. The second input is a step function introduced in the shunt field of the generator due to mutual inductance between armature and field windings; the corresponding time function is the inverse Laplace transform of equation 20.

The two terminal voltage transients will be equal and opposite if equations 23 and 24 are satisfied

$$\tan^{-1}\left(\frac{2\beta}{\alpha_r-\alpha_g}\right)+\tan^{-1}\left(\frac{2\beta}{\alpha_r+\alpha_g}\right)=2\tan^{-1}\left(\frac{2\beta}{\alpha_r+\alpha_g}\right) \quad (23)$$

where

$$\beta=\alpha_r\alpha_g(1+K_rK_p)-\left(\frac{\alpha_r+\alpha_g}{2}\right)^2$$

$$D_a=K_p\alpha_gM \quad (24)$$

where D_a is the rate of change of terminal voltage with armature current due to demagnetization effects, and M is the mutual inductance between armature and shunt field circuits.

Every effort is made to satisfy the criterion of equation 23 in the manufacture of voltage regulators; that is α_r is made much larger than α_g. In practical systems approximation, equation 23 is true to within about 4 degrees, which is negligible. Equation 24 can be shown to be true. Let us consider ϕ as a change from an initial reference value. Let e, i_f, and i_a be the corresponding changes from the initial values of terminal voltage, shunt field current, and load current, respectively. From equation 5 we can write

$$K_f=\frac{\partial e}{\partial i_f} \quad (25)$$

By definition

$$D_a=\frac{\partial e}{\partial i_a} \quad (26)$$

Therefore

$$D_a=K_p\frac{S\partial\phi}{\partial i_a} \quad (27)$$

where K_p = a constant of the generator and S is a constant generator speed.

But

$$\frac{\partial\phi}{\partial i_a}=\frac{M}{kN_f}=\frac{M}{L_f}\frac{\partial\phi}{\partial i_f} \quad (28)$$

where

N_f = number of turns in the field winding

k = a constant of proportionality between the field pole flux and the flux responsible for generated voltage

From equations 27 and 28

$$D_a=K_pS\frac{M}{L_f}\frac{\partial\phi}{\partial i_f} \quad (29)$$

Using equation 29 and the definitions of K_s and α_g given with equations 10 and 11,

$$D_a=MK_p\alpha_g\frac{K_pS\frac{\partial\phi}{\partial i_f}}{K_s} \quad (30)$$

From equations 25 and 30

$$D_a=MK_p\alpha_g \quad (24)$$

Therefore both criteria are satisfied and the two transients in question cancel each other.

RECENTLY there has been a heartening trend in biological research toward closer collaboration between the physical and the biological sciences. This paper is a résumé of a collaborative program of this type which is being pursued at the University of Pennsylvania. In order that such a program be well balanced, research, education, and instrumentation are all required.

Work done in the field of electrocardiography may be cited as one example of research. (This work was carried out with the Robinette Foundation of the Hospital of the University of Pennsylvania.) In explanation of the distribution of potentials on the body surface, arising from heart action, an ingenious theory has evolved which is widely accepted. However, some of the fundamental postulates on which this theory is based are open to question. Chief among these is the assumption that for electrocardiographic purposes, the body behaves as a homogenous volume conductor. Through the years numerous attempts have been made to check this assumption both by measuring directly the resistivities of the various tissues within the body and by more indirect means. Investigators have reached widely-differing conclusions from their experiments so that there is still no definitive answer to the question. This past work has been reviewed and evaluated[1] and at present a series of experiments is underway which, it is hoped, will further clarify the subject.

The educational phase of the program has been conducted at both the formal and the informal levels. Courses have been given in radiologic physics, physics applied to physical medicine, electrical instrumentation for research workers in the biologic sciences, electricity applied to electrocardiography, and lectures on the physical aspects of radioactivity applied to medicine. So far, the education of the engineering personnel has been informal in nature, although formal courses for physical scientists interested in the biologic sciences are being contemplated. It is felt, however, that the informal type of education for both engineers and medical men has been of considerable value, and it is considered that one of the important justifications for the entire collaborative effort lies in the opportunity provided for education of this type.

The third phase of the program consists of the development of instruments for physiological measurements. These instruments are tools for basic research in the medical field; therefore the engineering which goes into their development is considered an integral part of the medical research program. The remainder of this paper will concern itself with a description of specific instruments which have been devised for this purpose.

In order to study experimentally the functioning of a complex electric circuit, it is necessary to measure certain of its basic quantities, such as voltage, current, and impedance. Similarly, in any physiological system there also are certain basic parameters whose behavior must be studied to gain an understanding of the over-all functioning of the system. In this connection, temperature, blood pressure, and volume rate of flow of blood are regarded as particularly important. Much time has therefore been spent on the development of devices to measure these quantities.

In developing any measuring device, it is of prime importance that introduction of the device into the system shall not excessively alter the quantity to be measured. In biological work, this requirement is much harder to meet than in most of our physical instrumentation because the variables are very closely interrelated. Thus it is extremely difficult not to alter the normal behavior of the system when the measuring device is introduced. Furthermore, this complexity makes it difficult to trace the effect of altering one of the variables. For example, suppose the temperature of the skin is to be measured by means of a thermocouple. The direct approach would be to fasten the thermocouple securely to the skin. The fastening however, may exert pressure on the blood capillaries under the skin, interfere with blood flow, and so disturb the skin temperature. The fastening is also likely to interfere with sweating by stopping air circulation over the area covered leading once again to an alteration of the skin temperature it is desired to measure.

Temperature Measurement*

In measurement of body and skin temperature both thermistors and thermocouples have been used. Electrically, the thermistor is more convenient than the thermocouple for the following reasons:

1. A thermistor has a much higher impedance than a thermocouple (usually several thousand ohms as compared to a few ohms). Hence lead resistances and

Figure 1 (left). Bottom view of skin temperature measuring device with thermistor mounted at apex of lucite cone

Figure 2 (right). Thermistor assembly for use in measurement of deep tissue temperatures. To complete the assembly the wires are pulled back through the tubing until only the thermistor head protrudes

switch contact resistances are unimportant and it is not necessary to take special precautions in the wiring of associated circuits.

2. Because of its high temperature coefficient (−3 per cent per degree centigrade), a thermistor is approximately ten times as sensitive as a thermocouple when circuits with indicating devices of the same sensitivity are used for the comparison.

3. In a thermistor circuit it is not necessary to maintain a constant reference temperature.

4. Since the thermistor detects a change in temperature as a change in resistance, it may be incorporated in an a-c bridge whose unbalance may be amplified with an a-c amplifier before measurements. The thermocouple, however can produce only a direct voltage, and the d-c amplification required is difficult to achieve.

The thermocouple, however, has two distinct advantages over the thermistor:

1. It can be made smaller.

2. Its output voltage is approximately a linear function of temperature, whereas the thermistor is quite nonlinear.

In skin temperature measurement, the problems mentioned earlier have been considered in the design of the device shown in Figure 1. This particular unit contains a thermistor as the active element although the housing* is equally adaptable to a thermocouple. Because the thermistor itself is very small, 0.016 inch (Western Electric Company, type *V597*) it causes a minimum of interference with sweating when placed in contact with the skin. The housing is supported by the skin approximately one inch from the point at which temperature is to be measured. By adjusting the springs that hold the core to the outside ring, any desired degree of pressure may be obtained.

In another instrument using a radiation thermopile the influence of the measuring device on skin temperature has been reduced further. Such a unit has been combined with a direct-reading self-calibrating potentiometer to form an instrument that is capable of close measurements of skin temperature but which eliminates the necessity of physical contact with the body.

The thermistor also has been adapted to the measurement of temperature within the body.[3] Figure 2 shows a fine tube of polyvinyl chloride (outside diameter, 0.020 inch) with a *V597* thermistor mounted at its end. This tube is fine enough to be slid into a reasonably small (number 19) hypodermic needle. In use, the needle with the thermistor inside it is first introduced into the desired position. The needle is then withdrawn over the thermistor tubing leaving the thermistor exposed to the tissue.

A thermistor has also been incorporated in a device used to measure rectal temperature. If only a single determination of rectal temperature is required, a thermometer is the simplest solution to the problem. However, it is often required to continuously record rectal as well as other temperatures over a period of time and for this purpose both the thermocouple and the thermistor seem well suited.

The thermistor is thus seen to afford a simple and convenient means of measuring temperatures wherever it can be used. However, there are still some situations in which it cannot be used because of its size. For example, as a possible aid in the diagnosis and study of arthritis it would be useful to know the temperature of finger joints. For this purpose one must use the smallest clinically acceptable hypodermic needle to introduce the measuring device into the joint space. A number 25 hypodermic needle is considered to be the best compromise between size and mechanical strength. This has an inside diameter of approximately 0.009 inch, while the smallest commercially available thermistor, it will be recalled, has a diameter of about 0.016 inch, not including the necessary insulation and protective housing. So for this application a thermocouple is required.

A diagrammatic explanation of the thermocouple that was developed for this work is shown in Figure 3. It has been possible to make a thermocouple approximately 0.0037 inch diameter (one and a half times the diameter of a human hair) by use of a concentric layer construction. Its core consists of a 0.001-inch diameter enameled constantan wire from which the enamel is removed at one end leaving an exposed tip of constantan about 1/32-inch long. A thin layer of silver is deposited over the front half of the wire, making contact with the bare constantan at the end. This contact forms the measuring junction. Other constructional details are indicated in Figure 3. The reference junction at the back end of the thermocouple is placed in a small bottle filled with ice and water to form the cold junction, and finally two copper lead wires are brought out from the assembly to be connected to a recording potentiometer.

Since the thermocouple is very fine it is quite fragile and the special arrangement required to hold the ice bottle and the insertion needle in the proper positions with respect to the couple, is shown in Figure 4.

For possible use in measuring the temperature of the blood in capillaries, a unit of similar construction to the one just described, but having an over-all outside diameter of 0.0015 inch instead of 0.0037 inch, has also been constructed. However, this unit is extremely fragile.

Blood-Pressure Measurement

Blood pressure is conventionally measured by wrapping a rubber cuff around the arm and determining the minimum pressure required to stop flow. This indirect procedure yields information of considerable clinical value. However, much more detailed information may be obtained concerning the functioning of various parts of the blood circulating system by directly measuring the pressure

* The housing is a refinement of a commercial unit developed by the Revere Corporation of America, Wallingford, Conn.

Figure 3. Diagrammatic explanation of construction of fine wire silver-constantan thermocouple

of the blood within the heart and the blood vessels. An instrument[3,4] to perform this measurement was recently developed at the University of Pennsylvania through the joint efforts of the Johnson Foundation for Medical Physics, the Department of Physiology of the Medical School, and the Moore School of Electrical Engineering. This work was performed under a contract with the Office of Naval Research.

A plastic tube, called a catheter, is introduced through a hypodermic needle into the vessel under study. The instrument end of the catheter is led to a small chamber, one wall of which is a thin metal membrane. This movable membrane is spaced a short distance from a fixed metal plate, thus forming a capacitance. Small movements of the membrane, with respect to the fixed plate, are measured electrically as changes in this capacitance. The chamber and tube are filled with saline solution so that blood will not clot in the system. Pressure changes at the end of the tube in the blood vessel are transmitted by the liquid back to the movable membrane. The varying membrane capacitance is part of one leg of a high-frequency bridge whose degree of unbalance is a measure of change in capacitance, hence of change in pressure. This unbalance voltage, after amplification and detection, drives a Brush recording oscillograph, thus producing a graphical record of blood pressure against time.

The sensitivity of the device may be expressed in various ways. At maximum sensitivity a pressure change of 1 millimeter of mercury causes an output voltage change of 0.6 volt across a 1,500-ohm load.

An alternative expression of sensitivity is in terms of the volume of the fluid which must be supplied to produce a given output. The stiffness of the diaphragm is such that 10^{-7} milliliters of fluid enters the chamber for a pressure change of one millimeter of mercury. Hence the overall volume sensitivity is about 1.7×10^{-6} milliliters per volt. This small volume displacement results in good reproduction of fast transient wave shapes even when very small tubing is used between the source of pressure and the capacitance chamber.

Finally, the sensitivity may be expressed in terms of the capacitance variation. A figure of approximately 0.02 micromicrofarad per volt of output is typical.

Blood-Flow Measurement*

Blood flow is conventionally measured by one of two possible procedures. One is to measure the flow through a single vessel. The other approach, applicable to measurements on extremities, is to measure the total volume of blood flowing through a complete body member. This latter technique is known as plethysmography.

Let us suppose it is desired to measure the rate of blood flow into the hand. The hand is sealed into an air-tight chamber. A rubber cuff similar to the type used for measuring blood pressure is wrapped around the wrist. The cuff is inflated just enough to stop the blood flow through the veins leaving the hand, but not enough to retard arterial blood flow into the hand. The resultant rate of swelling will also increase the pressure inside the air-tight chamber to which a pressure recording device is connected. Thus, the rate of blood flow into the hand can be indirectly measured. The device is calibrated by introducing a known amount of liquid into the air-tight chamber.

A number of theoretical and practical objections to the technique of plethysmography can be raised.

The temperature change resulting from the introduction of the hand into the air-tight chamber causes a pressure change which may be of the same order of magnitude as the blood-flow pressure change to be measured. Also conventional plethysmographs are made of metal, and there may be measurable heat transfer through the walls of the device.

The air-tight chamber is usually connected to the pressure measuring device through a long rubber tube in which air is employed as the transmitting fluid. This introduces an unnecessarily long and possibly variable time constant into the system. Furthermore, the pressure is measured with a lever system actuated by a stretched rubber diaphragm. The power from the diaphragm is used directly to drive a pen across a piece of smoked paper or to cause a mirror deflection. Either system introduces mechanical uncertainty into the system and the pen drive takes appreciable power as well.

The sealing of the hand into the air-tight chamber is conventionally effected by passing the hand through a slit in a small rubber sheet. The sheet is then glued to the wrist. However, the pressure of the rubber on the arm restricts blood flow by an unknown and uncontrollable amount. It is difficult to make this seal truly air-tight. And, finally, because of the flexibility of the rubber, slight movements of the arm can be transmitted through the membrane to cause false readings.

Nevertheless, medical research men feel that information of clinical value can

Figure 4. Complete fine wire thermocouple assembly with insertion needle and ice water bath

Hypodermic needle is attached to sliding crossbar with semicircular cutout. The crossbar is locked in forward position for insertion, then withdrawn to allow fine thermocouple to contact surrounding tissue. A double exposure has been made to show the crossbar and needle in forward and withdrawn positions

* This work was aided by a grant from the National Foundation for Infantile Paralysis.

be obtained by plethysmography. Therefore, a plethysmograph was designed to eliminate as many of these objections as possible.

Temperature drift is compensated for by placing a thermistor in the chamber and using its output to buck out a portion of the signal from the pressure measuring transducer. The device is built of Plexiglass, with low heat conductivity to minimize heat transfer through the walls, and it incorporates large removable ground glass plugs so that the hand may have normal air circulation around it until immediately before the test.

Pressure change is measured by a differential transformer used as an electromechanical transducer. The movable iron slug of the transformer is connected directly to a diaphragm placed in a wall of the air-tight chamber. The electrical signal is amplified to drive a Brush recorder. This arrangement has the advantages of ruggedness, high sensitivity, and a small time constant.

Finally, the rubber arm seal is replaced by a cloth impregnated with paraffin. This seal can be made air-tight more easily; it is easy to attach; applies minimum constricting force to the wrist, and when hard it becomes stiff enough to keep small body motions from being transmitted to the measuring chamber.

In addition to the instruments just described, several others have been designed to perform more highly specialized functions. For example, a device has been developed to aid in the diagnosis of certain anatomical abnormalities occurring in the cardiovascular system. A part of the diagnostic procedure in such cases consists of taking X-ray pictures of the affected area. In order to show the contour of the heart or vessel wall, a small amount of a dye opaque to X-rays is injected into the blood stream. When the blood containing the dye reaches the general region to be studied, a series of pictures is taken to show the blood at successive points as it flows through the blood vessels in the area. The vessels then show up in sharp contrast to the surrounding tissue. If, for example, there should be an abnormal opening between two chambers of the heart, it will be made apparent in the X-ray film by the shadow of the opaque blood flowing through it.

To make use of this technique a device is necessary which will rapidly move an X-ray plate (cassette) into place, take a picture, move the exposed cassette out of the way, and move another unexposed cassette into position. The device developed for this purpose will handle seven cassettes, changing them at the rate of two per second. A timing device, however, allows exposures to be made with any desired interval of time between each successive exposure from one second to 30 seconds. This feature is necessary to allow the blood to reach the regions under investigation before any pictures are taken.

Work on several other interesting problems in this field is in progress but, unfortunately, none are yet at a stage that warrants description. However, the few devices discussed seem to bear witness to a heartening new trend in science; the drawing together of the physical and biological sciences for collaborative investigation of the enormously complex mechanisms of the body in the hope that these sciences working together may be able to unravel mysteries that have thus far withstood the attacks of each science working alone.

Automatic Feathering—To Reduce the Hazard of Aircraft Engine Failure at Take-off

WILFRED L. KERSHAW
ASSOCIATE AIEE

FAILURE of an aircraft engine in flight changes the propeller of that engine from a source of thrust to a parasitic source of drag. Present-day propellers, selected for the efficiency with which they convert tremendous horsepower into thrust with comparatively small blade area, absorb proportionately high horsepower when windmilling the engine. The propeller used on the Martin model 202 airplanes converts a maximum of 2 400 horsepower into thrust at take-off. The same engine and propeller combination exerts a drag equivalent to approximately 220 horsepower when being windmilled at take-off airspeed. In contrast, the drag of the propeller feathered is equivalent to 12 horsepower. Thus, it is evident that in the event of an engine failure, in addition to the immediate loss of half the thrust, a windmilling propeller steals approximately 10 per cent of the horsepower available from the remaining engine, reducing the net thrust to approximately 45 per cent of normal. With one propeller producing drag and the other producing thrust, a turning moment exists, tending to turn the airplane in the direction of the faulty engine.

Take-off is in some ways the most critical part of a normal flight. With most of the runway used, the airplane is normally gaining both speed and altitude, but has too little of either to permit any immediate landing maneuver. It is at this time that the pilot depends most on an uninterrupted flow of power from the engines. Of the multiplicity of instruments which confront the pilot, there may be none which will immediately and reliably tell him that one engine has ceased to deliver its share of thrust. Changes in directional and lateral trim are often the best indication of the trouble. Well-trained pilots generally diagnose the meager symptoms correctly, but the possibility of human error is definitely aggravated by the atmosphere of emergency resulting from engine failure during take-off. The proximity of the ground leaves no opportunity for recovery if the pilot feathers the propeller of the good engine. Such mistakes have occurred with disastrous results.

The automatic propeller feathering system described in this paper was designed to initiate the propeller feathering cycle soon enough after engine failure to limit propeller drag to that of a feathered propeller, thus providing the maximum possible thrust for the remainder of the take-off and the landing approach to follow. Automatic feathering allows the pilot to devote his full attention to trimming the airplane, completing the take-off, and planning the best approach procedure. Electrically, the automatic feathering system prevents the pilot from feathering the propeller of the good engine. The system to be described was designed for a 2-engine airplane and is based on 2-engine premises. Although the critical need for automatic feathering decreases as the number of engines increases, the device is capable of improving the reliability of all multiengine aircraft.

Performance

If, after an engine power failure, the propeller feathering sequence is started while the propeller is rotating faster than windmilling speed, and the propeller pitch is advanced rapidly enough so that actual rpm is maintained above windmilling rpm throughout the feathering cycle, part of the kinetic energy of the whirling engine and propeller can be converted into thrust to reduce the propeller drag during the feathering cycle to less than that of a feathered propeller. It has been determined experimentally on the Martin model 202 airplane that, if the feathering cycle is initiated within 2 seconds after an abrupt loss of power, the propeller drag during the complete feathering cycle, starting at the instant of engine failure, will be less than that of a feathered propeller. If feathering is delayed, 2.4 seconds after an abrupt engine failure, the windmilling propeller will start to produce drag, which will rapidly increase to full windmilling drag. Under the stress created by an engine failure during take-off, an average pilot requires 5 seconds or longer to initiate propeller feathering manually. After feathering has been initiated belatedly, the propeller will continue to produce a drag greater than that of a feathered propeller until the windmilling rpm corresponding to the changing propeller pitch is sufficiently less than actual rpm. Automatic feathering completely eliminates the time span during which the propeller drag exceeds that of a feathered propeller. This advantage of automatic over-manual feathering may well determine whether or not the take-off will be successfully completed.

Figure 1 shows a time history of an automatic feathering cycle recorded in flight at an indicated air speed of 120 miles per hour, at 100 feet altitude. One plot shows propeller rpm versus time.

Paper 50-210, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 3, 1950; made available for printing August 17, 1950.

Figure 1 (left). Time history of an automatic feathering operation in flight. Indicated airspeed 120 miles per hour, altitude 100 feet. The air-pressure curve shows the impact pressure in excess of that due to airspeed, measured aft of the feathering propeller

Figure 3 (above). Propeller control panel, showing the manual feathering switches, the automatic feathering selector switch, and indicator lights

The time required to feather the propeller was 9.7 seconds, including 1.7 seconds before initiation of the feathering cycle. The feathering initiation and full feather indications were obtained electrically. The second plot shows the impact pressure in excess of that caused by airspeed measured by a pressure rake installed just aft of the propeller. The latter curve shows that the propeller did not create drag while it was being feathered.

Sensing Engine Failure

Engine torque is used as the means of determining the need to feather a propeller. This method is applicable to any engine equipped with a torque nose; that is, where the propeller gearing is so arranged that the full engine torque is transmitted through a ring gear which is prevented from rotating by a series of pistons working in oil-filled cylinders. The oil pressure thus developed, called torque pressure, can be measured at an outlet provided on the propeller gear case at the forward end of the engine. The automatic feathering system is so arranged that when it is turned on and when normal take-off engine torque is expected, the propeller will be feathered if engine torque drops below a preset value.

Engine rpm cannot be used to indicate failure, because the windmilling rpm of the engine at take-off airspeed is within the range of rpm which might be obtained with a faulty propeller governor. Even though engine rpm is lowered by a faulty propeller governor, the engine would continue to deliver power and feathering would be undesirable.

Manifold pressure is likewise of no use as a failure sensing means, since it is proportional to engine rpm and throttle setting, and does not depend on the actual firing of the cylinders and development of power.

Figure 2. Phantom view of the airplane with the location of the major components of the automatic feathering system shown

Automatic Feathering System Design

The automatic feathering system used on the Martin model 202 airplanes was designed on the following premises:

1. The propeller of the engine should be feathered if, after an indication has been obtained that the engine is operating at

Figure 4. The automatic feathering relay box

take-off power and no change in engine controls has been made which would reduce engine power, it is determined that engine power has dropped below some prescribed minimum value and has remained below that minimum value longer than would be caused by a momentary engine cough or sputter.

2. The manual feathering system of one propeller should be rendered inoperative while the other propeller is being feathered automatically in order to eliminate the possibility of pilot error.

3. The automatic feature should be so designed that no component of the normal propeller feathering system need be redesigned.

4. A failure of the automatic feathering system should not interfere with the operation of the normal feathering system.

5. The pilot should be able to override the automatic system to unfeather the propeller if power is regained after feathering has started.

6. The automatic feathering system of the second propeller should be rendered inoperative after one propeller has been feathered either manually or automatically.

7. The automatic feathering system must not create any hazard or limitation during any feathering operation.

The following description of components of the automatic feathering system applies to the Martin model *202* airplane with Pratt and Whitney *R-2800* series engines and Hamilton standard propellers. In general, the system is applicable to any multiengine airplane equipped with engines each having a torque nose and propellers capable of being feathered.

The automatic feathering system, shown schematically in Figure 2, has four functions: arming, initiating, feathering, and remembering. They are performed as follows:

1. A throttle-operated snap-action switch, located in the engine control pedestal, provided to accomplish part of the arming function, indicates that the throttle is advanced to a position corresponding to low take-off power.

2. A high torque pressure switch, mounted directly on the engine, completes the arming signal when engine torque pressure exceeds 80 pounds per square inch (corresponding to 1,130 horsepower at 2,220 rpm), indicating the engine has achieved take-off power. The purpose of this switch is to preclude the possibility of inadvertent feathering during a throttle burst or during engine starting, at which time the throttle switch might be closed while torque pressure would be less than the setting of the low-torque pressure switch to be described later.

3. An arming relay is provided to maintain the armed signal as long as the throttle switch is closed, regardless of later torque pressure decrease below the initial arming value of 80 pounds per square inch. The system can be disarmed only by retarding the throttle to open the throttle switch or by turning automatic feathering off.

4. A low-torque pressure switch, mounted with the high-torque pressure switch on the engine torque nose, completes the automatic feathering signal when torque pressure drops to 30 pounds per square inch, provided the system has been armed.

5. A time-delay relay is used to prevent initiation of the feathering cycle for those cases in which the power loss is of a momentary nature. A delay of approximately 0.2 second, in addition to the time required for torque pressure to drop to 30 pounds per square inch, has been found to be the best setting.

6. A feathering relay shunts the normal feathering controls to complete the feathering cycle, blocks the manual feathering system of the opposite propeller, and closes the remembering relay.

7. A remembering relay interrupts power to the corresponding engine fuel booster pump and renders the automatic feathering system of the opposite propeller inoperative as long as the propeller remains feathered and the bus is energized.

8. A manual on-off selector switch, to deenergize the automatic feathering system when its protection is no longer needed, and three indicator lights, one to show power on, the others to indicate when each engine is armed, are grouped with the manual feathering switches within easy reach of both the pilot and co-pilot, see Figure 3.

9. The relays required for the 2-engine installation are located in the automatic feathering relay box located in the fuselage of the airplane. The box is provided with Cannon-type quick disconnects to facilitate testing and replacement, see Figure 4.

The Automatic Feathering Circuit

Figure 5 shows the complete automatic feathering circuit and the manual feathering and unfeathering circuits of the Hamilton Standard hydromatic propeller. In this variable pitch propeller, the pitch of the blades is controlled by the position of a piston, within the propeller hub, to which the blades are geared. In normal operation the position of the piston, and hence the propeller pitch, is controlled by a governor and valving arrangement using oil at moderate pressure provided by an engine-driven, small capacity pump, which is an integral part of the governor. To produce rapid pitch change while feathering and unfeathering the propeller, an electric motor driven pump of greater capacity, working at much higher pressure, is used, and the normal governor operation is by-passed.

The legend of Figure 5 will be used to designate the various relays and relay contacts in the following description of the operation of the circuit. The circuit is drawn with the propellers in normal operating pitch, throttles retarded, and torque pressure less than 30 pounds per square inch. The reversing circuits for the propeller are omitted because they have no effect on the operation of the automatic feathering system. The opera-

LA, RA—left or right arming relay. *LB, RB*—left or right time delay relay. *LC, RC*—left or right feathering relay. *LD, RD*—left or right remembering relay. *PU*—pick-up coil. *TD*—time delay coil. LR_1—left resistor number one (typical)

Figure 7 (above). Bench test panel to simulate flight operation of the automatic feathering relay panel

tion of the left engine circuits will be described.

With the selector switch off, all connections from the bus to the automatic feathering system are open and the engine fuel booster pump control relays are grounded through the selector switch. When the selector switch is placed in the *ON* position, the left fuel booster relay is grounded through normally-closed relay

Figure 6. Exploded view of the piston-type torque pressure switch

contacts LD_3, and power is available to the left throttle switch.

When the left throttle is advanced to a position corresponding to low take-off power, the left throttle switch closes, completing the circuit to contact *C* on the torque pressure switch. Note that even though the torque pressure switch is in the low-pressure position, no circuit is available to close the time delay relay *LB* to initiate the feathering cycle. As torque pressure rises to 80 pounds per square inch, the torque pressure switch closes on contacts *A* and *C*. The arming relay, *LA*, closes and is electrically locked in by its own contacts. This condition is indicated by the left armed indicator light. The purpose of the LA_1 relay contacts is to prevent an improper armed indication if some circuit element should present a resistance high enough to prevent relay *LA* from closing. The circuit is now armed and will feather the propeller if torque pressure should drop below 30 pounds per square inch. The circuit can be disarmed by opening the left throttle switch (by retarding the throttle) or by switching the selector switch to *OFF*.

Assuming the circuit is armed, if torque pressure drops to 50 pounds per square inch, the torque pressure switch will assume some intermediate position, opening the connection between its contacts *A* and *C*, but the circuit will remain in the armed condition. If torque pressure drops to 30 pounds per square inch, the torque pressure switch will close on contacts *A* and *B*, energizing the coil of the time delay relay, *LB*. After an 0.2-second delay, contacts LB_1 close, energizing the pick-up coil of the feathering relay, *LC*. Contacts LC_1 close to energize the holding coil of relay *LC* before contacts LC_4 open to de-energize relay *LC* pick-up coil. The resistor LR_1 is provided so that the *LC* relay may be dropped out by application of bus potential to the ground side of the *LC* relay holding coil during unfeathering. When relay *LC* picks up, the pilot is prevented from manually feathering the right propeller while the left propeller is being feathered automatically, and the pick-up coil of the remembering relay, *LD*, is energized.

Contacts LD_1 close to energize the holding coil of relay *LD* directly from the bus before contacts LD_4 open to de-energize the pick-up coil of relay *LD*. The resistor LR_2 provides a means to drop out the *LD* relay during unfeathering. Operation of relay *LD* starts the feathering pump, blocks the operation of the right engine automatic feathering circuits, de-energizes the arming circuit of the left propeller and the relay *LC* pick-up coil circuit, and opens the control circuit to the left engine fuel booster pump. This last operation does not deny fuel to the left engine since normally the left engine-driven fuel pump will be operating. Rather, the fuel booster pump is stopped to prevent loading the engine with fuel as the engine stops rotating.

With the circuit conditions just outlined, it is impossible to feather the right propeller manually or automatically.

As the feathering pump moves the blades of the left propeller to the full feathered stop, oil pressure increases to the value necessary to momentarily open the high pitch cutout switch (a Hamilton Standard manual feathering system component). While the high pitch cutout switch is open, the ground connection for the *LC* relay is removed and the *LC* relay drops out. The feathering pump stops, and the *LD* relay pick-up coil circuit is de-energized. Contacts LC_3 close, permitting operation of the right propeller *manual* feathering circuit.

The left propeller is feathered. The left remembering relay, *LD*, electrically locked in by the connection through its own contacts directly to the bus, will prevent operation of the left fuel booster pump as long as the selector switch is in the *ON* position, and will prevent operation of the automatic feathering circuits of either propeller as long as the bus is energized, unless the left propeller is unfeathered. The *LD* relay has no effect on the operation of the manual feathering or unfeathering circuits of the right propeller.

If the pilot desires, the left propeller can be unfeathered manually at any time during the automatic feathering cycle or after its completion. Assuming that the left propeller is being automatically feathered, it has been shown that the arming relay, *LA*, and the time delay relay, *LB*, have been dropped out, while the feathering relay, *LC*, and the remembering relay, *LD*, are in the energized position. If the left propeller manual feathering switch is pulled to the *UNFEATHER* position, the following events take place:

1. Terminals *D*, *G*, and *H* of the manual switch are energized by a connection to the bus through the left propeller control circuit breaker, terminal *A* on the switch, and the common switching connection within the manual switch.

2. The *D* terminal provides a new, direct source of power for the left feathering pump relay.

3. The *G* terminal provides power to actuate the left propeller solenoid valve. This valve, located on the propeller governor, reverses the oil flow to unfeather the propeller.

4. The *H* terminal serves to drop out relays *LC* and *LD*.

The manual feathering switch is held in the *UNFEATHER* position long enough for the propeller to return to its normally governed range where the propeller governor is then able to regain control. The automatic feathering circuits have thus been returned to normal and the circuits for each propeller will rearm providing the engines are at take-off power and the automatic feathering switch is in the *ON* position. Since the automatic feathering circuits have been returned to their normal condition, they will function as described previously. Either propeller will be automatically feathered if a further power failure should occur.

It can be seen that the propeller can be unfeathered after completion of the feathering cycle in a like manner, with the same results.

Manual feathering can be accomplished at any time, provided the propeller of the other engine is not being feathered automatically, by pushing the manual feathering switch to the *FEATHER* position. Terminal *D* of the manual switch energizes the feathering pump relay, initiating the feathering cycle. Terminal *F* energizes the pick-up coil of the *LD* relay which closes to block the automatic feathering system of the right engine and stop the left engine fuel booster pump. Terminal *C* energizes the manual switch holding coil, which holds the switch in the *FEATHER* position until the ground circuit to the holding coil is broken by the high pitch cutout switch at the completion of the feathering cycle.

Selection and Testing of Equipment

As is to be expected in the development of any new control system subjected to extreme environmental conditions, failures were experienced during the initial stages of development and testing. Failures of any sort could not be tolerated. A rigorous program of examination and testing of all components was undertaken. Components were redesigned and rebuilt as required; testing rigs suitable for use later in production and service were developed to aid in trouble shooting, and after suitable operation was obtained in flight and on the ground, all components of the system were subjected to environmental requirements well in excess of those expected on the airplane. Within four months after the first circuit was

drawn, the first production units had flown 75 hours and had completed hundreds of automatic feathering operations during take-off and in flight at all altitudes from sea level to 6,000 feet. The testing and design of the major components in the system is described in the following paragraphs.

Relays

A standard air dash-pot type time delay relay proved adequate since the limited altitude range within which the automatic feathering system operates has little affect on the timing function of the relay. During the initial testing a drift in the delay setting was found. This drift was prevented by sealing the time delay adjustment screw.

Rotary-type relays, with 5-pole double-throw wafer-type contacts, were selected for feathering relays and remembering relays. During the test program it was found that the relays would hold-in on coil voltages as low as 0.5 volts of direct current. This condition was not tolerable because of the unfeathering operation. The magnetic parts of the rotor of the relay were chrome plated to raise the drop-out voltage to a minimum of 5 volts of direct current. To prevent dropout during bus voltage transients, the relays are required to hold-in at 12 volts direct current.

A standard aircraft quality, double-pole double-throw relay was selected for the arming relay. No trouble has been found in its operation.

The complete automatic feathering relay box, Figure 4, was subjected to a 50-hour vibration test at normal and elevated temperatures. While being vibrated at a frequency of 2,500 cycles per minute and a total amplitude of 0.031 inch, the automatic feathering circuits were cycled every two minutes with simulated normal load at the output terminals. The first 40 hours of the test were conducted at room temperature, while the last ten hours were conducted in an ambient of 165 degrees Fahrenheit. The test was completed without failure in two days and two hours.

Torque Pressure Switches

After a careful study of the available pressure switches, the piston-type torque pressure switch now used was designed. The construction of the piston switch is illustrated in Figure 6. A piston made of an insulating material is balanced between oil at engine torque pressure and a calibrated balance spring. The piston carries a brass, bridging contact ring, which makes contact with (1) the common contact leaf at all times, (2) the low-pressure contact leaf below 32, ± 2 pounds per square inch oil pressure, and (3) the high-pressure contact leaf above 75, ±5 pounds per square inch. The piston and spring, the various contact leaves, and the electric connector and wiring are assembled in a split shell aluminum alloy housing. The bottom face of the housing fits the standard engine torquemeter pad. The top face is made similar to the engine torquemeter pad for the installation of a torquemeter transmitter if desired. The housing is drilled with suitable oil passages to permit oil flow to and from the piston and the torquemeter pad atop the housing.

The slow-moving, sliding contacts of the piston switch are well suited for their required duty. The high pressure contact closes the circuit to the arming relay coil which draws approximately 0.1 ampere at 28 direct volts. The low pressure contact closes the time delay relay coil circuit whenever the automatic feathering system is tested or whenever engine failure occurs during take-off. The time delay relay coil draws approximately 0.3 ampere at 28 direct volts. After initiating the circuit, the contacts do not carry or break any current. Long contact life is expected.

The piston switch was subjected to a 100-hour vibration test under the same conditions described in the relay control box test previously outlined. During the 100-hour period, the switch was cycled approximately 9,200 times at normal electric load. The high and low pressure settings varied over a maximum range of 2.5 pounds per square inch. No contact pitting or wear was visible after completion of the test. The switch is not affected by vibration or high ambient temperature and exhibits no tendency to chatter.

After soaking at a temperature of −40 degrees Fahrenheit for a period of 4 hours at a pressure of 80 pounds per square inch, the low-pressure switch contact closed 1.1 seconds after releasing the oil pressure. The results of the test were deemed satisfactory, since the test was conducted without the benefit of vibration and it is unlikely that the oil temperature in the torque nose would be as low as that tested after engine warm-up, even in extreme ambient conditions.

During the test program it was found that an improperly-bled fluid-type torquemeter transmitter can cause a low-pressure switch closing delay of as long as 15 seconds. The use of an electric transmitter is recommended on aircraft employing the automatic feathering system if a torquemeter is required.

Propeller Feathering Components

No change of design of any of the components furnished with the propeller was required.

Some minor troubles in the manual feathering equipment, of little consequence when feathering manually, were found during the automatic feathering test program. Hamilton Standard Propeller Division engineers and service representatives gave willingly of their time and experience to isolate and correct the difficulties.

Flight Testing and Service Performance

Two complete sets of automatic feathering system components were built for the initial flight test program. The components were flown alternately, one set of equipment being flight tested, while the second set was being reworked or equipped with redesigned parts to eliminate troubles isolated on previous flights.

To facilitate trouble shooting, a test box was developed for observation of the progress of the feathering cycle in flight. Two groups of indicator lights, one for each propeller, were arranged so that the lights came on in sequence during normal operation of the automatic feathering system. Improper light sequence isolated the source of system trouble. The test box was connected to the circuits to be observed by inserting a short length of cable between the automatic feathering relay control box disconnect receptacle and the airplane wiring disconnect plug. Thus the test box could be installed or removed readily.

Bench test arrangements were built for ground checking all major components of the system before flight. The bench test panel, developed to facilitate ground testing of the automatic feathering relay panel, was later used as a production test fixture. The test panel, shown in Figure 7, simulated the operation of all other components of the manual and automatic feathering systems.

After all deficiencies had been eliminated, the design was standardized and the final evaluation was begun. During the final evaluation program the system was subjected to a cycling test and an accelerated service test. During the cycling test, repeated engine failures were simulated in flight. The system successfully completed 100 automatic feather operations in succession in one day's flying. During the accelerated

service test, a 75-hour cross-country airplane service performance test without maintenance, engine failures were simulated 11 times.

During the final flight test evaluation and the more than two years of commercial airline service to date, there is no known instance of the automatic feathering system failing to feather a propeller when such action was indicated or inadvertently feathering the propeller of an engine when such action was not required.

Conclusions

Automatic propeller feathering after engine failure is one of a series of electromechanical devices which are providing increased safety of flight. It automatically detects an engine failure, selects the faulty engine, and corrects the deficiency, eliminating windmilling drag and its detrimental effects during take-off. It prevents the fatal error of feathering the wrong propeller. It allows the pilot to devote his full attention to maintain his flight pattern, and to plan his proper approach procedure. It allows improved airplane operating economy by increasing the safe gross weight at take-off.

The automatic feathering system used on Martin model *202* airplanes was designed to give trouble-free performance with a limited amount of maintenance. Much thought was given to make the system easy to service, free of periodic failures, and to provide a fail-safe design which would not interfere with the normal feathering system.

Aircraft operators, both civil and military, look askance at each new electromechanical device. Their confidence can be gained only by consistently faultless performance. The automatic feathering system used on the Martin *202* airplane achieved faultless performance after a development period of less than a year. The success of the system is due to careful evaluation during the early design stages, followed by thorough testing before production. Such a program is essential before the designers of aircraft electric equipment can win and maintain a reputation for providing equipment which works the first time, every time.

No Discussion

Aluminum Conductors from an Aircraft Manufacturer's Viewpoint

W. W. SCHUMACHER
NONMEMBER AIEE

WEIGHT is one of the major factors in aircraft design and any reliable means of weight reduction must be thoroughly exploited. Since substitution of aluminum for copper conductors offers appreciable weight savings, especially in view of the continuing increase in the size and power of aircraft electrical systems, the development of reliable means for using this material has received considerable attention in the past few years.

The designer of aircraft electrical systems is very limited in the amount of weight that he can save. Aside from choosing the lightest components, the only other weight economy that he can control is the cable weight of his system. Since the cable weight of recent military and commercial aircraft is approximately 32 per cent of the total electrical system weight, weight reductions of 40 to 100 pounds may be readily realized by the use of aluminum cable and bus bars.

Aluminum cables and bus bars have been used successfully for the past 50 years and have been thoroughly proved in regard to their electrical and mechanical characteristics.[1] However, these installations have been primarily in the fields of high voltage power distribution, electric railways, and heavy industrial loads. Use of insulated aluminum cable on aircraft in lower voltage distribution systems is comparatively new and has required considerable development and testing to obtain reliable means for termination and joining.

Comparison of Aluminum to Copper Conductors

In comparison to standard annealed copper wire of the same size, the hard drawn wire of aluminum electrical conductor material suffers from a somewhat lower tensile strength: 23,000 to 32,000 pounds per square inch for aluminum versus 30,000 to 35,000 pounds per square inch for copper. However, the conductivity of aluminum is only 61 per cent that of copper and to obtain equivalent resistance, in general, two American Wire Gauge sizes larger aluminum cable must be used. Experimental data and service experience have shown that hard-drawn aluminum cable compares favorably in all respects to annealed copper cable of the equivalent current carrying capacity. This is true in regard to breaking strength, flexibility, and vibration.

The weight of electrical conductor aluminum is only 30.2 per cent that of copper. For equal resistance, an aluminum cable must be 62 per cent larger in cross-sectional area than the corresponding copper cable. Even with this increase in size, the aluminum conductor will have only 49.4 per cent the weight of an equivalent copper conductor. Thus, when considerable lengths of cable are used, especially in the larger sizes, a very worth-while saving in weight can be obtained. The data just mentioned is based on a bare conductor. Because of the larger size of aluminum cable required, the weight of insulation will be somewhat more than for a comparable copper cable. Thus, in the smaller size cables the weight which can be saved is considerably reduced because the insulation comprises a larger percentage of the cable weight. Table I compares typical aluminum and copper cables, showing the weight actually saved per 1,000 feet and the percentage of copper cable weight saved. In aircraft applications, the use of aluminum cable smaller than number 8 is currently not considered advantageous.

Rectangular bar, rod, tubular, and structural shape aluminum conductors have demonstrated satisfactory performance for many years as bus bars in high-voltage transmission and heavy industrial installations. The bus-bar requirements in aircraft electrical systems are for the most part rectangular bars of the smaller sizes. As with cable, an aluminum bar will be 62 per cent larger in cross section but will weigh only 49.4 per cent as much as a copper bar of the same electrical resistance. Figure 1 shows the standard

Table I. Comparison of Typical Aluminum and Copper Cables

Cable Size		Weight, Pounds Per 1,000 Feet		Weight Saved, Pounds Per 1,000 Feet	Saving, Per Cent

sizes of aluminum bus bars used in one manufacturer's aircraft and the comparable standard sizes of copper bus bar for equivalent current carrying capacity.

Weight Saved by Use of Aluminum Conductor

Obviously the total amount of weight which can be saved by the use of aluminum conductors depends on the size, the voltage, and the extent of the system in which it is used. The larger the airplane and the more extensive its electrical system, the greater will be the saving in weight. In the past the high-voltage a-c power employed in airplane systems was comparatively small and could be handled by the smaller size wires not justifying substitution of aluminum. Therefore aluminum cable has been used mostly in the low-voltage d-c systems. Recent increases in the high-voltage a-c power requirements for radio, radar, fire control, and other special equipment now make it desirable to use aluminum in the a-c as well as in the d-c circuits. Table II shows the actual weight saving accomplished by use of aluminum conductors in the design of several recent types of aircraft.

Problems Encountered in Use of Aluminum Conductor

Aluminum cable is so similar to the copper cable of equivalent current carrying capacity in mechanical characteristics, method of manufacture, and insulation that no change is required in the design of installation of electrical systems. The problems which have required considerable development and testing have been in obtaining terminal connections with satisfactory resistance and temperature-rise characteristics. These problems arise primarily because of the rapid oxidation and susceptibility of aluminum to corrosion by contact with copper in a damp, or salt, atmosphere.

Table II. Aircraft Weight Savings by Use of Aluminum Conductor

Aircraft Type	Total Weight of Electric Equipment and Cable (All Copper), Pounds	Weight of Cable (All Copper), Pounds	Weight of Copper Cable that may be Converted to Aluminum, Pounds	Weight of Aluminum Cable, Pounds	Weight Saved by Using Aluminum Cable, Pounds
2-Motor Commercial Transport	1,183	351	89	52	37
Light Bomber	1,102	343	131	68	63
Patrol Plane, Primary System 30 volts direct current	1,861	684	312	180	132
Patrol Plane, Primary System 120/208 volts alternating current	2,240	668	202	134	68

When exposed to air, aluminum quickly becomes coated with a thin film of oxide which acts as an insulator. In stranded cable this oxide forms not only on the cable surface but on all of the strands as well. This causes a transverse resistance between the inner strands and the cable surface which must be overcome if satisfactory joining and termination of cables is to be accomplished. Because of this transverse resistance, the breaking of a few strands at the cable surface, which come in contact with the terminal barrel, may be considerably more serious than with copper cable. Therefore greater care is being used to avoid cutting or nicking the strands when stripping insulation for terminal application.

The corrosion encountered is of two types: first, the building up of oxides or salts at the cable to terminal contact surface; and second, the electrolytic corrosion which occurs where aluminum terminals contact other metals, such as the brass nuts or studs frequently used on electrical equipment. These corrosive effects must be minimized if low resistance connections are to be maintained over a satisfactory period of time. The use of silver-plated aluminum bus bars on tin-plated copper bus bars, together with cadmium-plated steel bolts, nuts, and washers in contact with tin-plated aluminum terminals, has given excellent performance.

In early postwar efforts to adapt aluminum cables and terminals to aircraft use, difficulty was experienced with high-resistance terminals and terminals in which the resistance increased excessively with age or corrosion. Extensive development and tests have been devoted to overcoming these troubles. It now appears that the early failures were due primarily to the use of soft aluminum cable, inadequate terminal installation procedures, and faulty plating of the terminals.

Development of Satisfactory Terminals

Types of Terminal

Terminals for aircraft cable must be small in size, light in weight, easy to attach, and possess good mechanical strength. Most terminals fall under the classifications of welded, soldered, clamped, or pressure-applied fittings. Although welding terminals to cables provides a good permanent joint, problems of expense, convenience and burning of insulation must be overcome. In spite of the use of special solders and fluxes, soldering of terminals to cables has not proved satisfactory. In particular, difficulty has been experienced with soldered terminals in overcoming the transverse resistance and obtaining sound connections to the inner strands. Clamped fittings providing the surface area and pressure necessary for satisfactory joints suffer from disadvantages of size, weight, and atmos-

Figure 1 (left). Maximum allowable current capacity for various aluminum and copper bus bars

Figure 2 (right). Types of aluminum terminals

pheric exposure at the connection with subsequent oxidation.

Of the pressure-applied terminals the two general types are the longitudinally indented and the circumferentially swaged, cross-section views which are shown in Figure 2. Either of these, when properly applied, will provide a satisfactory connection. The longitudinal indent permits a wide latitude in acceptable cable cross-section for a given maximum and minimum pull-out force. In the longitudinal indent the strands are drastically reshaped wiping off the oxide coating. The U-shaped cross section of the longitudinal indent appears to maintain its shape against relaxation of pressure and springback and provides a mechanically strong terminal, thus contributing to satisfactory operation in service. Less pressure, and therefore lighter equipment, is required to install the longitudinally-indented terminal. Pressure-applied type terminals should be made of electrical conductor grade aluminum so the lug and cable will have the same coefficient of expansion and rate of recovery after compression.[3] This minimizes creep of the cable and loosening of the joint which results in high-resistance connections. However, aluminum is malleable and cold flow of the terminal tongue must be considered. The tongue may be distorted on installation and may continue to flow with consequent reduction in contact pressure and increase in resistance. The longitudinally-indented type terminals are manufactured from aluminum tubing which becomes work-hardened during its forming stages. This work-hardening renders the terminal less susceptible to cold flow when subjected to the pressure of installation hardware. The use of aluminum terminals having the largest practical contact areas, fastened with steel bolts, nuts, washers, and heavy split-type lock washers, has overcome these difficulties satisfactorily.

Special tin-plated connectors are available for connection of aluminum to copper cable and for connection of aluminum cable to Army-Navy type plugs and receptacles. The former consists of a copper cylinder with an aluminum barrel attached at one end for indentation on the aluminum cable and a copper barrel of the correct size attached at the opposite end for indentation on the equivalent copper cable. The latter consists of an aluminum barrel for indentation on the aluminum cable with an integral aluminum pin for soldering into the Army-Navy connector. While worthy of further development, these adaptors have not yet met the stringent requirements for aircraft use. A recommended procedure is to carry copper cable from Army-Navy connectors, or other equipment requiring its use, to the nearest terminal block where it can be connected to the aluminum cable using standard terminal lugs.

Use of Joint Sealing Compounds

Although the wiping action from rearrangement of strands in the longitudinally indented terminal helps reduce the transverse resistance of aluminum cable, it was found that further means were required to obtain completely satisfactory and reliable terminal installations. Investigation indicated that use of a joint sealing compound, such as a petrolatum jelly containing zinc dust, would reduce the transverse resistance.[3] This compound is used to coat the inside of the terminal barrel and is forced up between the strands of the cable. When the terminal is indented onto the end of the cable, the particles of metallic zinc break through the oxide coating and form low-resistance current paths from strand to strand and from cable to terminal. The petrolatum jelly acts to prevent reformation of the oxide which would increase the terminal resistance with age.

Plating of Terminals and Bus Bars

Plating of aluminum terminals prevents the formation of oxide on the terminal and reduces the effect of electrolytic corrosion between the terminal and other metals to which it may be attached. Early tests of unplated, copper-plated, and zinc-plated terminals indicated that zinc plating of the aluminum terminals provided the most satisfactory results, as shown in Glenn L. Martin Company laboratory tests. Although these tests indicated the superiority of zinc-plated terminals, it was found that in use the contact surfaces turned black and high-resistance connections occasionally resulted. At a later time, tin-plated terminals became available and have been shown both by test and experience to give satisfactory performance without these aging characteristics.[4] At first, considerable trouble was encountered with peeling of the tin plating. However, improved plating methods have overcome this difficulty.

Aluminum bus bars for aircraft use also require protection from the effects of

oxidation and corrosion. It has been found that silver plating affords very satisfactory service in this respect. Silver-plated aluminum bus bars have been used in one manufacturer's aircraft for five years without any reports of trouble. Silver-plated bus bars are used because the facilities for the process were available and perfected before the advent of tin-plated terminals. Tin-plated bus bars would undoubtedly also offer good service. Bare aluminum bus bars are not recommended unless special precautions are used to remove the oxide from the area in contact with the terminal, and coating this surface with a compound which will prevent reoxidation. The bus-bar material that offers the highest conductivity is electrical conductor grade aluminum.

Other materials such as $2SO$, $2S^1/_2H$, and $2SF$ may be used but their lower conductivity should be taken into consideration.

Terminal Installation

In practice, terminal lugs are cleaned of oxide, plated, filled with compound, and the barrels are sealed by the manufacturer. On installation the seal is removed and the cable is pressed into the barrel, forcing the compound in between the strands of the cable. Improved performance resulting from better distribution and deeper penetration can be obtained by forcing the compound into the cable with a grease gun just prior to terminal installation. Portable hydraulic tools and pneumatic bench tools are available for indenting the terminal barrels.

Taping Cable to Terminal Joint

Another practice which has proved to be beneficial is taping of the cable to terminal junction. After installation, the joint is tightly wrapped with vinyl electrical tape, covering a good area of the cable insulation and all of the terminal barrel. By sealing in the compound and sealing out the air, the tape prevents reoxidation of the aluminum and corrosion at the cable-to-terminal junction.

Standards of Acceptability

The accepted method of determining the reliability of a cable-to-terminal connection is by measuring the voltage drop across the terminal and the temperature rise of the terminal when subjected to the rated current of the cable. To determine the effects of aging and corrosion, samples are subjected to these measurements immediately after terminal installation, after an aging period, and at intervals during exposure to corrosive atmospheres or liquids. A maximum voltage drop of 20 millivolts and a maximum temperature rise of 70 degrees Fahrenheit have been used arbitrarily as standards of acceptability after careful consideration of the requirements of aircraft electrical systems. While the optimum voltage drop and temperature rise will vary for different sizes of cable and terminals, these values were adopted for all sizes used in order to simplify inspection procedure (Laboratory tests, Glenn L. Martin Company).

Development and Tests

It appeared that in attaching compression-type terminals, the depth of indent used would be the criterion of connection quality, since it determines the amount of pressure and wiping effect on the strands. Figure 3(A), the cross section of an improperly indented terminal, shows the poor contact between strands resulting from low indenting pressures. Figure 3(B) shows the cross section of a properly indented terminal for comparison. Figures 4(A) and 4(B) illustrate samples of good and poor indentation in regard to position of the indent. Work curves have been prepared similar to Figure 5, for longitudinally-indented terminals applied to various sizes of aluminum cable (Laboratory tests of the Burndy Engi-

Figure 5 (left). Work curve indentation versus relative conductivity and tension for failure

Figure 6 (right). Effect of joint sealing compound

Figure 7. Location of needle point probes for voltage-drop measurement

Figure 8. Depth of indent measurements

neering Company, Inc.). The tension for failure increases with depth of indent to a maximum and then decreases. To the left of the peak, the connection fails because the cable pulls out of the terminal. To the right, the cable strands are damaged by excessive pressure and break under tension. In general, the relative conductivity (ratio of terminal conductivity to conductivity of an equal length of cable) reaches a maximum in the vicinity of the maximum tension for failure and is better than 100 per cent in this region. These data have been of great value in standardizing the depth of indent for optimum terminal installation on the various sizes of cable and for specifying the maximum and minimum acceptable indentations listed in Table III.

To determine the effects of joint sealing compounds a test was run in 1946 using pressure-applied terminals of number 1/0, number 2 and number 4 gauge cables (Glenn L. Martin Company Laboratory tests). Measurements were made after alternate periods of salt spray and outdoor exposure of various samples using zinc compound, commercial compound, and no compound. The increase in voltage drop throughout the corrosion tests was smallest for the combination of longitudinally-indented terminals and zinc compound and was well within the acceptable limit of 20 millivolts. The curves for the number 2 gauge cable are shown in Figure 6. It is of interest to note that this performance was achieved with annealed cable, zinc-plated terminals, and no protective taping.

To determine the effect of taping the cable-to-terminal joint, tests were made of two samples each of number 4 cable from five manufacturers. The terminals of one sample of each type were taped with vinyl electrical tape. Millivolt drop and temperature rise data were taken and the ends of each sample were then submerged in a saturated sodium chloride solution for three weeks. After thorough drying, the readings were repeated. In general the results showed somewhat better performance for the taped terminals.

Voltage-drop measurements may be made by pressing two needle point probes at a predetermined separation, one into the terminal tongue and the other through the insulation into the conductor as shown in Figure 7. This method has the disadvantage of the conductor being damaged if the probes are not carefully inserted. The use of a tool which limits the depth of probe penetration eliminates this danger and assures consistent millivolt readings.

Complete test records of depth of indent and voltage drop have been kept on all aluminum cable for 19 ships of one type of airplane. Table IV shows samples of this data picked at random from the test reports. For ease and accuracy of measurement, depth of indent is taken as the thickness remaining at the bottom of the indent, as shown in Figure 8, rather than the depth from the original outline to the bottom of the indent.

The material and installation improvements that have been made in the past five years have added considerably to the reliability of aluminum cables and terminals to the point where their use should not create any skepticism. In fact, soft aluminum cables with zinc-plated terminals which were installed five years ago in aircraft are still giving reliable service.

Standard Procedure for Cable Assembly

As the result of many tests, only a few of which have been discussed, the following procedures have been developed by one manufacturer for the use of aluminum cable in aircraft. For all cable sizes number 8 and larger, aluminum cable may be used except in the following service, for which the use of aluminum cable is not recommended. In nacelles forward of the engine fire walls, as connections to shock-mounted equipment; and as connections to equipment subject to frequent service or replacement. These are applications where frequent bending or large vibrations may occur and complete reliability of aluminum cable and terminals for such use has not been fully proved to their satisfaction.

Hard-drawn electrical conductor aluminum cable complying with government specification *AN-C-161*, and meeting additional requirement that no absorbent wrapping be used next to the conductor, is recommended. This is done to prevent moisture from being carried back under the insulation and corroding the conductor. To simplify cable inspection a 10-inch sample, stripped of insulation,

Figure 10(B) (right). Hydraulic-indenting portable tool

Figure 11(A). Millivolt-drop bench tester

Figure 11(B). Millivolt-drop portable tester

may be weighed to insure that sufficient metal is present to carry the specified current. The sample weight is checked against a minimum acceptable weight which has been established for each size cable. Several strands then are taken from the cable and their tensile strengths are measured to insure compliance with specifications.

Cables may be cut to the desired lengths using a swing-type power saw, which minimizes possibilities of burring or displacing the strands. The cable end is placed in a clamp and zinc petrolatum compound forced into the cable by means of the grease gun shown in Figure 9. The proper length of insulation then is removed, using a hot blade cable stripper which removes insulation cleanly without danger of cutting or nicking the strands.

The cable is inserted in a terminal holding a finger over the inspection hole to prevent escape of compound from the barrel. The assembly is placed in the pneumatic bench tool (or portable hydraulic tool) shown in Figures 10 (A) and (B), and indented, using the proper die and closing distance. The terminal then is visually inspected for position of the indent. The thickness remaining at the bottom of the indent is checked with a dial micrometer to determine that it falls within the acceptable maximum and minimum shown in Table III. The cable-to-terminal joint then is subjected to a millivolt drop test with the equipment shown in Figures 11 (A) and (B). The cable end to be tested is clamped in the machine, which insures good contact of the cable and needle point probes at the specified separation. The other end is clamped to a power supply and the current is adjusted to the rated value for the cable size. The voltage drop then is read from the meter, and if it exceeds 20 millivolts the terminal is rejected. This inspection procedure is recommended because the use of aluminum cable on aircraft is relatively new to most electricians. After a reasonable indoctrination period when successful assembly procedures have been definitely established, the millivolt-drop measurement may be discontinued. However, a terminal depth of indent measurement should be made on each assembly to assure that the proper indenting dies have been used.

Temperature-rise measurements can be made with relatively simple equipment. Cable samples to be tested are connected in series and thermocouples are clamped to the terminals. Terminal temperatures are measured and rated current then is applied to the cables until the temperature stabilizes. Terminals showing more than a 70 degrees Fahrenheit rise are rejected. The effects of drafts can be eliminated by surrounding the test rack with an enclosure. Because of the time required for setup and temperature stabilization, temperature-rise measurements are not made on all cables of a production run. This test is recommended only as a quality control sampling procedure.

After the tests just mentioned, the terminal barrels are taped with approximately $2^1/_2$ turns of 3/4 inch by 0.010 vinyl adhesive tape, making sure to seal the gap between the insulation and terminal barrel at one end and the inspection hole at the other. The needle probe holes in the cable insulation adjacent to the terminal are self-sealing and are not detrimental in any manner. Electrical leakage is either nonexistent or insignificant at the voltage levels currently used in aircraft power systems.

Portable indenting and voltage drop measuring instruments are used when the installation must be made in an airplane. "Go" and "No-Go" type gauges some-

times are used in place of the micrometer for checking depth of indent.

Maintenance

Because of the similarity of installations, maintenance procedures established for copper cable will suffice for aluminum cable. The only change recommended is more frequent inspection of terminal connections to assure that bolted connections have not become loose and that heat discoloration of the terminal or the cable insulation adjacent to the terminal has not taken place due to a poor connection. With more actual operating data on types of installation, specific inspection periods can be established.

Future Developments

While satisfactory methods of applying aluminum cable to aircraft electrical systems have been demonstrated and such cable is being used as standard equipment in aircraft, efforts are continuing to improve the reliability and useability of this material. With more experience as to the effect of vibration, it is felt that it will be safe to specify aluminum cable in a few locations noted previously where it is not now being used. Further development of techniques for welding terminals to aluminum cable could make this method practical for production use. The good correlation between voltage-drop and depth of indent in the process presently standardized indicates that it may be possible to eliminate the voltage-drop test and control manufacturing quality from the depth of indent alone. Another improvement now under development is an insulation sealing terminal. The barrel of this terminal is extended in a larger diameter to cover the end of the insulation. This extension is crimped onto the insulation at the same time the terminal is indented into the cable. In addition to sealing the terminal to cable junction, this terminal distributes vibration or bending loads to the insulation, thereby reducing the possibility of cable breakage at the junction. Such developments point the way to even wider and more satisfactory use of aluminum cable with possible extension to include use of smaller gauges in the future.

Analogue Techniques for Turbojet Thrust Instrumentation

E. S. VAN VALKENBURG
NONMEMBER AIEE

N. W. MATTHEWS
MEMBER AIEE

THE THRUST of a turbojet engine is the primary parameter indicating engine performance, but it is not directly measurable during flight. By simplification of the thermodynamic function of momentum thrust, gross thrust can be determined during flight by simple automatic metering and computing techniques. A prototype model of this computer has been constructed and evaluated at the Naval Research Laboratory.

In contrast to the large scale computers functioning in many of the nation's laboratories, a great number of surprisingly compact, light weight, special purpose computers are being designed and used for control or instrumentation computations. The large scale computer is inherently large physically in order to perform a multitude of mathematical operations, and thus is applicable to an infinite variety of problems. Special purpose computers are usually of the analogue type in which as many parameters as possible are held fixed permitting only certain specified solutions.

Analogue computing principles are readily adaptable in control systems by transforming physical measurements into the required input variables by appropriate transducers. Likewise, the output of the computer can operate an actuator in a control system or automatically record the specified solutions. Thus, one envisions a completely automatic system of measurements, calculations, and actuation.

A recent application of such a special purpose computer, which has been developed at the Naval Research Laboratory, is a thrust computer for turbojet engines. This device is rather simple as compared to many other applications. However, this simplicity is due largely to the analysis of the function which was to be solved. It will be shown that the theoretical function involved in this application is quite complex, but simplification of this function without sacrificing accuracy, resulted accordingly in simpler, more compact, and comparatively inexpensive equipment. The purpose of this paper is to present the formulation of the thrust functions and analogue techniques utilized in this special computer.

Requirements of a Thrust Computer

Effective operation of military aircraft requires instrumentation which includes an indication of engine performance. With the introduction of turbojet aircraft came the demand for instrumentation which includes a means for determining the engine's thrust. Thrust is the primary parameter indicating turbojet performance, but the components of thrust are not directly measurable during flight. Therefore, thrust must be computed according to the thermodynamic properties of the engine.

Those thermodynamic functions are unavoidably complex. Thus, the pilot of a turbojet aircraft is not capable of accurate interpretation of engine performance when provided only with instruments indicating the parameters from which thrust can be computed. As a result, it is necessary to apply automatic computing techniques to thrust determination during flight. Such an automatic computer based on analogue principles can instantaneously and continuously solve the thermodynamic equation for thrust and thus indicate the thrust of a turbojet engine directly with a single instrument reading. This will facilitate flight test programs and enable a pilot to determine engine performance with a degree of precision not presently possible.

The net thrust, F_n, developed by a turbojet engine is the resultant of the gross thrust, F_g, measured at the exhaust nozzle and the ram-drag, F_r, occurring at the air intake.

$$F_n = F_g - F_r \tag{1}$$

Net thrust is directly measurable only for engines at rest. Thus, when a jet aircraft is in motion net thrust must be computed from equation 1 where gross thrust and ram-drag are thermodynamic functions. The principal component of net thrust indicating turbojet performance is gross thrust. Gross thrust instrumentation for test of turbojet aircraft has involved lengthy computations from data recorded upon a photo panel during test flights. Naval establishments concerned with flight test programs have found it desirable to record and/or indicate the instantaneous gross thrust continuously during flight evaluation operations. The analogue computer which has been designed for this purpose meets weight and space requirements for jet aircraft installation and could be adapted easily as a gross thrust indicator for operational aircraft. A prototype model, hereafter called the jet thrust computer, has been constructed and evaluated under controlled laboratory conditions.

Gross Thrust Measurements

The gross thrust of a turbojet engine can be expressed as a function of total, P_{tj}, and static, P_{sj}, pressures at the exhaust nozzle and the ambient pressure, P_a. Let the effective area of the exhaust nozzle in the region of pressure measurements be A_j, and let the ratio of specific heats at the exhaust be γ_j. The deriva-

Figure 3 (right). A division operator

tion of gross thrust from the thermodynamics of ideal adiabatic expansion of the exhaust gases gives

$$F_g = A_j P_{sj} \frac{2\gamma_j}{\gamma_j - 1}\left[\left(\frac{P_{tj}}{P_{sj}}\right)^{\frac{\gamma_j - 1}{\gamma_j}} - 1\right] +$$

Momentum Thrust Term

$$A_j(P_{sj} - P_a) \qquad (2)$$

Pressure Thrust Term

These pressures can be measured through pressure probes in the form of a rake across the exhaust or by single total and static probes critically located in the exhaust nozzle to give close approximations to integrated values of pressure.

Equation 2 can be simplified for the purpose of designing an analogue computer without sacrificing accuracy by expanding the bracketed portion of the momentum thrust term into an infinite power series of P_{tj}/P_{sj}. This is possible since γ_j remains nearly constant over usual operating conditions. This expansion gives

$$\left(\frac{P_{tj}}{P_{sj}}\right)^{\frac{\gamma_j - 1}{\gamma_j}} - 1 = \sum_{n=0}^{\infty} K_n \left(\frac{P_{tj}}{P_{sj}}\right)^n \qquad (3)$$

where K_n' is the coefficient of the nth term. A satisfactory empirical representation can be obtained using the first three terms of such a power series as is evident from Figure 1, curve "A". The maximum deviation of the empirical curve from the theoretical curve within the range of Mach numbers 0 to 1 is ± 0.3 per cent. Substituting these first three terms of the series in equation 2 and multiplying each K_n' by $2\gamma_j/(\gamma_j - 1)$ to become K_n gives the simplified equation for gross thrust.

$$F_g = A_j\left[K_1 P_{sj} + K_2 P_{tj} + K_3 \frac{P_{tj}^2}{P_{sj}} + K_4(P_{sj} - P_a)\right] \qquad (4)$$

where K_4 is equal to the unity coefficient of the pressure thrust term.

Pressure-Potential Analogue

An analogue computer has been designed to provide continuous solution of equation 4 for gross thrust. This is accomplished by establishing analogues between pressures and electrical potentials in such a way that voltages proportional to each of the four terms of equation 4 are developed for any conditions of pressure parameters. The sum of these four voltages, which are connected in series, is then proportional to the gross thrust.

The methods of multiplication used in this computer are flux linkages (transformers) and mechanical displacements applied to potentiometers. Consider the simple circuit shown in Figure 2(A) as a multiplication operator. The input voltage e_1 is applied to a potentiometer (R_1) through a transformer whose secondary-to-primary turns ratio is $C_2/C_1 = C' = a$ constant. The wiper arm of this potentiometer is displaced linearly with pressure P_1. If the impedance R_2 is much greater than R_1, then $e_0 = e_1 C' k P_1 = e_1 C P_1$ where k relates pressure and wiper arm displacement. Therefore, this circuit performs two multiplication operations in series.

Any function e_1 is multiplied by a constant and a variable.

This analogue can be expanded to perform multiplication of a function by two variables by employing R_2 as a second potentiometer as shown in Figure 2(B) and controlling the displacement of this second potentiometer by a pressure P_2. Then

$$e_0 = e_3 k P_1 k P_2 = e_3 k^2 P_1 P_2 \text{ provided that } R_3 >> R_2 >> R_1$$

The operation of division is accomplished using a negative feedback amplifier similar to the circuit shown in Figure 3. This amplifier has a large amplification (G). Then $e_0 = -e_g G$. Let the displacement of the wiper arm on the potentiometer across the output of the amplifier be D then $D = kP_3$. Then $e_g = e_i + De_o$. Eliminating e_g gives $e_o = -e_i G/(1 + DG)$. If G is sufficiently large

Figure 4. Schematic diagram of a gross thrust computer

that $DG >> 1$ over the range of values D then

$$e_o = \frac{-e_i}{D} = \frac{-e_i}{kP_3}$$

Fundamentals of a Gross Thrust Computer

The jet thrust computer utilizes a system of the foregoing analogues for computing gross thrust. Conversions of pressures to electrical potentials are obtained by linear, low-torque potentiometers which are connected by direct mechanical linkages to pressure sensing bellows. A simplified circuit diagram of the gross thrust computer is shown in Figure 4. The equation to be solved is composed of four terms all multiplied by the area, A_j. An analogue of A_j is obtained by an autotransformer, T_v, which is adjusted so that the line voltage of the aircraft E_L, is converted to a voltage proportional to A_j. This voltage is applied to a special transformer T_R designed to introduce the required constants K_1, K_2, K_3, and K_4 by proper turn ratios between each of its secondary windings. The outputs of these secondaries are applied to a system of pressure transducers indicated in the diagram by the pressure actuated potentiometers. Then the voltage appearing between ground and the lowest sliding contact is

$$V_1 = A_j K_1 k P_{tj} \tag{5}$$

The second term is obtained in the same manner as the first except that this transducer is controlled by P_{tj}.

$$V_2 = A_j K_2 k P_{tj} \tag{6}$$

The third is a more complex function and requires a combination of operations. The total pressure is squared by using two potentiometers in series, Figures 2(B), with both wiper arms being driven by P_{tj}.

$$V_i = A_j K_3 k^2 P_{tj}^2$$

This voltage, V_i is applied to the feedback amplifier circuit, Figure 3, which divides V_i by $k\ P_{sj}$ or

$$V_3 = A_j K_3 k \frac{P_{tj}^2}{P_{sj}} \tag{7}$$

The final term is generated by use of a differential pressure transducer. The wiper arm displacement in such a transducer is proportional to the difference of two applied pressures. This displacement is $k\ (P_{sj} - P_a)$, and

$$V_4 = A_j K_4 k (P_{sj} - P_a) \tag{8}$$

Adding these four voltages in series produces a voltage between ground and output lead of

$$V_o = kA_j\left[K_1 P_{tj} + K_2 P_{tj} + K_3 \frac{P_{tj}^2}{P_{sj}} + K_4 (P_{sj} - P_a)\right] \tag{9}$$

or

$$V_o = kF_g \tag{10}$$

A voltage indicator measuring V_o can be calibrated linearly in units of gross thrust.

The Jet Thrust Computer

The prototype model of the jet thrust computer is designed for operation from a 115-volt 400-cycle source. The 400-cycle supply was chosen for this model since that frequency is normally available in military aircraft. This type of computer could be designed for operation at another frequency by proper design of the transformers. The output voltage of the computer is directly proportional to the line voltage. To eliminate effects of line voltage variation ratio-type indicators may be used for indicating the thrust.

Figure 6. Gross thrust computer

Figure 7. Experimental apparatus to determine computer accuracy

This type of current measuring instrument has two current coils which give a deflection proportional to the ratio of currents. The current sensing movement of megger instruments is of this type. The computer output current is rectified by a half-wave crystal detector and applied to one of these current coils. A portion of the line current is applied through a matched crystal to the other coil of the ratio instrument, a variation of ±50 per cent in the line voltage was not detectable on such a thrust indicator. Simultaneous recording of computer output and line voltage could be used for a continuous recording of thrust without a ratio-type indicator.

A complete circuit diagram of the jet thrust computer is shown in Figure 5. The system of pressure transducers is shown at the left in the diagram. Six pressure measurements are necessary. These include two static pressure measurements, three total pressure measurements, and one differential pressure measurement. Two systems of transducers were investigated. The first system, purchased from a private contractor, used only three pressure sensing units. A static pressure unit was designed such that a single set of pressure sensing bellows produced sufficient torque to drive two potentiometers connected in tandem. The total pressure unit was similar in that one set of bellows operated three potentiometers. The differential pressure unit was of conventional design. This system was employed in an attempt to decrease space requirements as compared to a system of six individual transducers each having its own pressure sensing elements. However, recent developments in small size transducers do not make such compounding necessary. Compact units of the order of 2-inch cubes now are available commercially. A second system of transducers using six single units was obtained recently. This system actually requires less space than the first system.

Rheostats are connected in series with three of the secondaries of the ratio transformer to compensate for a slight nonuniformity among the transducers. The amplifier for the dividing circuit is composed of a high-μ pentode resistance-capacitance coupled to a power pentode. These electron tubes and the power supply rectifier are miniature types. The gain is approximately 300 with no external feedback. The internal feedback path across the power stage through R_4 and C_4 was found necessary for stabilization throughout the external feedback range.

The autotransformer for introducing the effective area of the exhaust nozzle could be eliminated if the computer were designed for a specific type of turbojet engine having a fixed effective area. The constant A_j could then be included in the design of the ratio transformer or instrument calibration. For those turbojet engines having variable exhaust area, the movable arm of the autotransformer could be automatically controlled through a mechanical linkage to this area control.

Figure 6 shows the complete analogue computer for computing gross thrust. The amplifier and ratio transformer are mounted on the 7-inch square chassis. This chassis is larger than necessary to facilitate work upon circuitry during tests. The 6-unit transducer system is shown mounted compactly in a 4-inch square box. This computer equipment weighs about 16 pounds, exclusive of the weight of connecting cables and plumbing which depends on the actual aircraft installation. The weight of the computer could be decreased to less than ten pounds for operational aircraft instrumentation. After the computer has been initially adjusted for a particular type engine, no further adjustments should be required.

Laboratory Evaluation of the Jet Thrust Computer

The prototype model has been evaluated by controlled laboratory measurements. This evaluation was conducted in two phases. First, it was desirable to determine the limits of accuracy of the complete analogue computer without including errors due to transducer characteristics. The results of these measurements indicated an actual evaluation of the analog principles used in the thrust computer. This was accomplished by use of calibrated potentiometers which could be adjusted manually for feeding equivalent pressure data into the computer. These potentiometers were assembled in ganged units similar to the 3-unit trans-

ducer system. Figure 7 shows this equipment as assembled for momentum thrust computations. Typical momentum thrusts, as computed by this equipment, are shown in Table I. The maximum errors introduced by the empirical representation of thrust and analogues are ±0.61 per cent. Therefore, the accuracy of the jet thrust computer should be largely a function of the accuracy of the transducers.

Measurements of the transducer characteristics (pressure versus displacement) for each potentiometer indicated a linearity to within ±2 per cent. There also exists an error of ±0.5 per cent maximum due to a hysteresis effect observable between increasing and decreasing pressure variations.

The complete transducer system was connected through a series of manually-controlled needle valves to a source of compressed air. In this manner controlled constant pressures could be applied to the jet thrust computer simulating independent total and static pressures. Ambient pressure was simulated for various altitudes by a controlled vacuum line. These pressures were measured with aircraft manifold pressure gauges which were calibrated against a mercury manometer. Gross thrusts as calculated according to the original thermodynamic equation for steady-state conditions of total, static, and ambient pressures were compared with the computer outputs. Table II shows typical results for the six single-unit system. The simulated exhaust pressures indicated in Table II are values taken from data recorded on a *FH-1* during flight. The two columns of measured thrusts in Table II indicate the minimum and maximum thrusts observed for any given set of conditions during repeated measurements. Therefore, the column of errors shown are the maximum errors observed during a series of tests. The average error observed was of the order of ±3.5 per cent. The average error using the ganged system was about ±2.5 per cent. These errors may be reducible in the future through improved design of low-torque potentiometers.

A study of the operation of the jet thrust computer in a turbojet installation has not been completed to date. The prototype model will be installed on a turbojet engine mounted on strain gauges in a test cell for evaluation of the thrust computer against strain-gauge indicated gross thrust.

Ram-Drag Measurements

An analysis of ram-drag at the air intake of a moving turbojet engine is incomplete at the present time. Several theories, varying in basic concepts, have been proposed, yet no particular theory is generally accepted. However, the jet thrust computer has certain properties that makes it applicable to certain types of ram-drag measurement. These possibilities will now be presented.

The jet thrust computer is adaptable to investigating ram-drag when it is assumed that ram-drag is a function of the gas velocities at the entrance of the air intake and that these gases behave adiabatically. Under these conditions it can be shown that the relationship between total and static pressures at the intake and ram-drag is similar to momentum thrust of the exhaust gases. Explicitly

$$F_r = A_4 P_{si} \frac{2\gamma_i}{\gamma_i - 1}\left[\left(\frac{P_{ti}}{P_{si}}\right)^{\frac{\gamma_i - 1}{\gamma_i}} - 1\right] \qquad (11)$$

This equation is the same as for the representation of momentum thrust except that the exhaust parameters are replaced by intake parameters. γ_i varies only to a second order with ambient temperature and can be assumed constant. If P_{ti}/P_{si} is plotted against

$$\left[\left(\frac{P_{ti}}{P_{si}}\right)^{\frac{\gamma_i - 1}{\gamma_i}} - 1\right]$$

for $\gamma_i = 1.40$, one obtains curve "B" in Figure 1. A determination of empirical constants for the power series representation of this function yields a characteristic which is within ±0.5 per cent of the original function within the range of gas velocities between Mach numbers 0 and 1. It was found that the ratios between these empirical constants and those determined for momentum thrust can be considered constant for all practical purposes, that is, $K_1'' = CK_1'$, $K_2'' = CK_2'$ and so forth, where $C = 1.15$.

Thus it may become possible to compute ram-drag on the basis of gas velocities at the air intake with the jet thrust computer. This is accomplished by using a jumper to by-pass the pressure thrust components and introducing the constant ratio (C) by the autotransformer. Figure 5 shows the simple circuitry for bypassing the pressure thrust components. The bypass cable is connected from $A_1B_2C_2$ to $A_1'B_2'C_2'$ instead of to the terminals of the differential transducer The resistor R_1 has the same resistance as the potentiometer P_1 for maintaining a balanced load on the ratio transformer.

If it is established in the future that ram-drag can be measured in the manner discussed, then net thrust can be measured during flight by connecting two jet thrust computers (gross thrust and ram-drag) in series opposition. The voltage developed across this combination should be proportional to net thrust.

No Discussion

Dynamic Characteristics of Carbon Pile Voltage Regulators

ROBERT L. MILLS
MEMBER AIEE

THE dynamic characteristics of voltage-regulated d-c electric systems are generally determined by empirical tests. By these tests one learns how the particular generator-regulator combination tested behaves, but the questions of how the regulator might work with another generator and how the regulator might be changed to improve the system operation are unanswered. In order to find an analytical method of answering these and other questions concerning the system operation a detailed study of the system was inaugurated at the Naval Research Laboratory in Washington, D.C.

Early in the study an opinion was formed that since the automatically-regulated electric system comprises ac losed loop it should be subject to analysis by the frequency spectrum method which had been devised for and advantageously applied to the analysis of servomechanisms and other obviously closed-loop systems. To realize the advantages of using this method it was found that a transfer function had to be defined for each system component and that the definition was not arbitrary. A transfer function is simply the ratio of an output variable to an input variable, but the input and output quantities of a particular system component must be those variables which are related to each other in this way: the output quantity must depend solely on the input quantity which in turn must be completely independent of the output except through the operation of the other components in the closed loop. The complete dependence of a component output quantity on the input variation makes it possible to study a component independently of the rest of the system and to determine a unique transfer function for the component. A transfer function defined as the ratio of the two quantities which satisfy the discussed criterion is a description of the behavior of a component regardless of the system in which the component is used. Simple graphical or analytical methods can be used to determine the operation of any system when all the component transfer functions are known.

Considering the variables involved in the operation of an electric system regulated by a carbon pile voltage regulator led to the conclusion that a proper transfer function for the regulator would have to be defined as the ratio of carbon pile resistance variations to regulator operating coil voltage variations. Resistance variation as an output quantity was recognized as an unconventional consideration to say the least, but a necessary one also. What other variable quantity which might be considered to be the regulator output would be unaffected by whether or not the carbon pile was connected into the field of a generator? And what other quantity would be unaffected by whether the generator with which the regulator is used is a low or high field current machine?

Having accepted this definition of regulator transfer function as a proper one, the next step was to obtain an expression for the function in terms of the constants of the regulator. This expression was derived from a regulator analysis which is described in detail in the body of this paper. It is based on the assumptions that deviations of the regulator variables from average values are small enough that the regulator can be considered linear and that variable frequency sinusoidal voltages are applied to the regulator operating coil. The regulator transfer function is therefore a function of frequency. Curves of amplitude and phase of the function versus frequency are presented in Figures 5 and 6.

In order to verify the validity of the transfer function expression it was necessary to measure a regulator transfer function. Doing this was by no means a simple matter. It was soon found that, in the neighborhood of the normal operating voltage, pile resistance is so sensitive to changes in voltage it is impractical to attempt to operate the regulator in its normal range in any situation in which feedback is not employed to make the operating coil voltage depend on pile resistance. The standard voltage regulated electric system is one in which the regulator can be operated normally, but use of this system for making transfer function measurements was prohibited by the difficulties involved in causing variable frequency sinusoidal voltages to occur across the regulator operating coil, and in measuring the amplitude and relative phase of the resulting pile resistance variations. Since there was no record of anyone's previously designing a system for making measurements similar to those we wanted to make, our only alternative was to design and build a system for the purpose. The system which finally operated as desired is described in detail in this paper. Electronic amplifiers are used to provide the feedback necessary to cause the regulator to operate normally and provisions were made in the design of the circuit so that a desired input signal can be easily impressed and so that resistance variations can be easily measured.

A plot of a regulator transfer function measured while the regulator was operated in this system is presented for comparison with the predicted curves in

Paper 50-213, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 5, 1950; made available for printing August 23, 1950.

ROBERT L. MILLS is with the Magnolia Petroleum Company, Dallas, Texas.

This paper was prepared while the author was at the Naval Research Laboratory, Washington, D. C. and portions were done in partial fulfillment of the requirements for the degree of Master of Science at the University of Maryland.

Figure 1. Section view of typical carbon pile regulator

Figures 5 and 6. The general agreement of the curves substantiates the validity of the analysis of the regulator from which the transfer function expression was derived. The disagreement of the two curves is attributed partially to the fact that, as yet, no method of determining the effective values of all the regulator constants has been devised.

The regulator analysis and the transfer function measuring system presented in this paper constitute the work done by the author on the "regulator section" of the study of the entire voltage regulated electrical system. Further studies of the regulator, a study of the generator transfer function, and methods of combining the transfer functions of the regulator and generator to obtain the system operating characteristics is continuing at the Naval Research Laboratory. Some of the progress made along these other lines is presented in a paper by Donald G. Scorgie entitled Transient Analysis of a Voltage-Regulated Aircraft D-C System.[1]

The order of presentation of the regulator analysis and the measuring circuit description is the reverse of the order in which they were mentioned in this introduction. The description of the measuring circuit is presented first to spare those who are just interested in a method of finding how a particular regulator works from a description of a mathematical argument to show why the regulator behaves as it does. Those interested in the mathematics of the situation will be pleased to note that the description of the circuit, though first, is brief.

General Description of Carbon Pile Regulator

Before discussing either the method of measuring the carbon pile regulator transfer function or the regulator analysis let us make sure everyone knows just what the carbon pile voltage regulator is. It is an electromagnetic device employing magnetic coupling between the electrical and mechanical parts. The most important parts are a stack or pile of carbon disks, a spring which has a soft iron armature attached to its movable end, and an electromagnet. Figure 1 is a diagram showing the arrangement of these parts in a typical regulator.

Here is how the regulator works. The spring exerts a force on the armature to compress the pile of carbon disks and reduce the pile resistance. The electromagnet and the reactive force of the pile oppose the force of the spring. The motion of the armature depends on an unbalance of these forces and the armature is stationary only when the force of the spring in one direction equals the forces of the pile and the magnet in the other direction. The spring and magnet are designed so that there is only a very small range of forces for which the spring force and the magnet force even approximately balance. This range corresponds to the small range of operating coil voltages in the vicinity of the desired regulating value and over this range of voltages the pile resistance varies from its maximum to its minimum useful values. For lower applied voltages (hence lower magnet forces) the balance of forces on the armature is attained with high pressure on the carbon pile and hence extremely low pile resistance. Figure 2 shows the type of carbon pile resistance versus electromagnet or operating coil voltage characteristic to be anticipated from a regulator designed in this manner. When the regulator is used to control the terminal voltage of a generator, the carbon pile is connected in series with the shunt field of the generator and the generator terminal voltage is applied to the regulator operating coil. It can be seen that if stability criteria are satisfied, the generator voltage will build up when the machine is first started to approximately the desired voltage and will then be stopped by the sudden increase in pile resistance. A desirable characteristic of the regulator is that it have high resistance sensitivity to voltage variations in the vicinity of the desired voltage. A particular advantage of a regulator that operates like the carbon pile regulator does is that the regulating action is made independent of the source of disturbance to the system.

Measurement of Regulator Transfer Function

High sensitivity of pile resistance to voltage variation which is necessary for most desirable regulating action was mentioned previously in this paper as the regulator characteristic which makes operating the regulator for study in some sort of feedback arrangement necessary. Figure 3 is the schematic diagram of an electronic feedback circuit that was devised for use with a 28-volt regulator. When the regulator is operated in this system its operation about any desired operating point in its normal operating range can be studied. You can see from the circuit diagram that once the regulator is operating at a desired resistance value that value of resistance will be automatically maintained. If the pile resistance tends to increase, for example, the electronic amplifier will make the regulator operating coil current increase and by the action of the regulator the resistance will be returned to its initial value. The initial desired value of pile resistance is set by means of one or both of the 50-ohm potentiometers shown in series with the carbon pile.

Figure 2. Idealized d-c characteristic of regulator

The principal advantages of measuring the regulator transfer function and otherwise studying the regulator operation while the regulator is operated in this system are the ease with which variable frequency sinusoidal voltages can be applied to the regulator operating coil and the ease and accuracy with which pile resistance variations can be measured. By applying the output of an audio or low-frequency oscillator to the input terminals noted on the diagram of Figure 3, a disturbance of any desired frequency or amplitude can be applied to the regulator operating coil. The magnitude of the disturbance to the regulator can be measured at the operating coil. The resistance in series with the carbon pile was made so large that the current through the carbon pile remains practically constant. The voltage across the carbon pile is proportional to the carbon pile resistance. The regulator output can then be simply found by dividing the alternating voltage measured right across the carbon pile by the current through the pile. The voltage variations across the pile are in

phase with the pile resistance variations, so the phase angle of the regulator transfer function which is the phase of the resistance variations relative to the a-c voltage across the operating coil can be measured by finding the phase angle of the a-c pile voltage relative to the a-c operating coil voltage. Measuring the same quantities while the regulator is operated with a standard generator would certainly not be this simple.

Figures 5 and 6 are plots of transfer function amplitude and phase versus frequency. The data for one curve in each figure were obtained while the regulator being tested was operated in the circuit of Figure 3. Voltage amplitudes were measured at the specified locations by standard methods and phase angles were calculated from measurements of Lissajous figures displayed on an oscilloscope. To make sure that the incremental inductance of the regulator operating coil did not vary with frequency, a measurement of total flux change was made at each frequency and maintained at a constant value. This measurement was effectively made by measuring the open circuit voltage induced in a coil wound concentrically with the operating coil. Since the voltage induced in this coil should vary linearly with frequency if the total flux change through the coil is constant, it was possible to insure constant flux change by adjusting the magnitude of the disturbance to the regulator at each frequency so that the auxiliary coil voltage varied linearly with frequency. This auxiliary coil, incidentally, is standard equipment on most carbon pile regulators. It is the coil which is ordinarily used for adjusting the division of load between two or more regulated generators operated in parallel.

During the tests of the regulator it was found that the transfer function depended on the average operating point to which the regulator is set for making measurements and on the input magnitude for small magnitudes. Dependence of the transfer function on the operating point can be attributed to changes in the incremental values of the regulator constants with operating point. The other dependence of the transfer function is probably due to changes in the incremental inductance of the operating coil. This inductance depends on the average slope of the minor hysteresis loop in the iron circuit. In typical regulators the inductance appears to reach a maximum value when an output of roughly 5 rms ohms is obtained and the transfer function is constant for greater disturbances.

The linearity of the regulator operation was criticized only by observing the wave shape of the output quantity on the oscilloscope, but surprisingly little distortion was noted over what was considered to be very wide deviations of the regulator variables from their average values. No distortion was noted while the data plotted in Figures 5 and 6 were being obtained as rms input voltages as high as 0.75 volt were used at the higher frequencies and rms resistance variations as high as 5.35 ohms occurred at the lower frequencies.

The shape of the transfer function curves shown in Figures 5 and 6 might have been surprising to those taking the data had the analysis of the regulator in which we had some slight confidence not been conducted previously. Is it not somewhat surprising, though, to notice that at one frequency (the frequency at which the phase shift is 180 degrees) as the regulator operating coil voltage increases decreasing pile resistance indicates that the armature moves away from the electromagnet? Obtaining reasonable explanations of how situations like this can come about is what makes analysis interesting.

Determining the Transfer Function by Analysis

The fact was pointed out in the general description of the regulator and illustrated in Figure 2 that the pile resistance versus operating coil voltage curve was characterized by a rather sharp break at some voltage below the normal operating voltage range. This break is necessary for achieving a very high sensitivity in the desired voltage range and adjustment of its location on the voltage axis is a convenient method of setting the voltage at which the regulated system operates. This break, however, must be disregarded if we are to analyze the regulator on the assumption that it is a linear device. In order to do this all d-c components of variables must be eliminated and only variations about arbitrary reference values considered. When only these variations are considered the assumption is tacitly made that the reference values are attainable. In other words the analysis we are conducting will be useful in determining the behavior of a regulated aircraft electric system which is disturbed by something such as the removal or application of load after it has first reached a stable condition. If the system never reaches the first stable condition, its dynamic behavior after a certain disturbance is of little interest anyway, so, by considering only variations about reference values, only knowledge of interesting systems which have once been stable will be obtained. A further linearizing assumption, that all deviations

Figure 3. Schematic diagram of measuring circuit

from reference values are small enough that they are proportional to the quantity which caused them, will be made.

The correlation between the frequency characteristics and the transient behavior of linear systems has received sufficient publicity that it need not be repeated here, but because it does exist sufficient information to determine the regulator behavior when subjected to any disturbance will be at hand when its frequency characteristics are known. For this reason the object of the regulator analysis might be stated to be the determination of the regulator frequency characteristics. Whether the result of the analysis be called the frequency characteristics or the transfer function is actually unimportant, since hairs have to be split to distinguish between the two terms. What is important, since analytic results can be checked by comparatively easy tests, is that the regulator can be analyzed on the assumption that the input quantity is sinusoidal. Under this assumption, and according to the definition of transfer function given in the introduction, the transfer function, symbolized by T_r, is

$$T_r = \frac{R}{\epsilon}(\omega)$$

where R and ϵ are sinusoidal variations of carbon pile resistance and operating coil voltage, respectively, and ω is the angular frequency of the sinusoidal applied voltage.

To obtain the desired expression in terms of the regulator constants a solution to the differential equations describing the behavior of the regulator must be obtained. The regulator has already been described as a device involving motion of mechanical parts and current in an electrical circuit. For this reason two equations are necessary to describe the regulator behavior; one dealing with the electrical elements, the other with the mechanical elements. The one dealing with the electrical circuit can be an expression of the fact that the sum of the voltage drops equals the applied voltage. The one dealing with the mechanical parts can be an expression of the fact that the sum of the forces applied to a mass equals the inertia force. Noting that voltage drops are due to the resistance and rate of change of flux linkages of the operating coil and that forces are applied to the armature by the electromagnet, the spring, and the carbon pile, the two equations can be written

$$E_o + \epsilon = R_c(I_o + i) + N\frac{d\phi}{dt} \tag{1}$$

$$F_M + F_s + F_p = M\frac{d^2x}{dt^2} \tag{2}$$

where

$E_o + \epsilon$ = applied voltage
E_o = desired reference operating coil voltage
ϵ = instantaneous variation in operating coil voltage
$(I_o + i)$ = operating coil current I_o and i having definitions analogous to E_o and ϵ, respectively
R_c = resistance of the operating coil circuit
N = number of effective turns in the operating coil
ϕ = total flux crossing the air gap and linking the operating coil, expressed in webers
F_m = force of the electromagnet
F_s = force of the spring
F_p = force of the carbon pile
M = effective mass of the moving armature
x = instantaneous deviation of the armature from its reference position
t = time

Viscous damping of the armature due to air is disregarded in equation 2. That it was negligible was verified by measuring the transfer function of a regulator operated in an evacuated chamber.

The signs of the forces of the magnet, the spring, and the pile can be determined only after an arbitrary decision has been made concerning positive displacement of the armature. So, let displacement toward the magnet be positive. Then by reference to the regulator diagram of Figure 1 it can be seen that forces of the magnet and the carbon pile are positive while the force of the spring is negative. All of these forces are functions of armature position. The force of the magnet, however, is also a function of the operating coil current and cannot be written in an expression as simple as those for the spring and the carbon pile. A detailed expression for the magnet force is presented later.

The regulator has been assumed to be a linear device so the expressions for the spring and pile forces can be assumed to be

$$F_s = -F_{0s} - K_s x \tag{3}$$

$$F_p = F_{0p} - K_p x \tag{4}$$

where F is used as a symbol for force, x for displacement of the armature from its reference position as above, and K for proportionality constants. The subscripts, s and p, refer to the spring and the pile, respectively, and the zero before the subscripts indicates the value of the quantity represented when the displacement (x) is zero.

The signs of the reference values of forces are seen to agree with previous conclusions concerning these signs. The signs of the proportionality constants were determined by simple reasoning. The negative force of the spring increases with positive armature displacement so the sign of the proportionality constant must be negative. The positive force of the pile decreases with positive armature displacement so the sign of the constant must be negative.

Substitution of these expressions for the spring and pile force in equation 2 gives

$$F_M + (F_{0p} - F_{0s}) - x(K_s + K_p) = M\frac{dx^2}{dt^2} \tag{5}$$

Equations 1 and 5 apply to the regulator simultaneously, but they cannot be solved until the total number of variables is reduced still further. The number of dependent variables can be reduced to two by first expressing the flux as a function of operating coil current and armature position and then expressing the magnet force as a function of the expression for flux.

If the assumption is made that the reluctance of the iron in the flux path is negligible in comparison to the reluctance of the air gap, the flux can be expressed as a function of the operating coil current and the air gap reluctance

$$\phi = N(I_o + i)/Rel_{AG} \tag{6}$$

where Rel_{AG} is the air gap reluctance in meter-kilogram-second units. The air-gap reluctance is proportional to the air-gap length and can be expressed as

$$Rel_{AG} = 2(s - x)/\mu A \tag{7}$$

where

s = distance from the pole face to the surface of the armature when $x = 0$
A = effective area of the air gap (in practice very nearly the pole piece area), and
μ = permeability of the air gap, and equals $4\pi \times 10^{-7}$ in meter-kilogram-second units

From equations 6 and 7

$$\phi = N(I_o + i)\mu A/2(s - x) \tag{8}$$

Letting i and x equal zero, we obtain the reference flux

$$\phi_0 = \frac{NI_oA\mu}{2s} \tag{9}$$

The flux is a continuous function of i and x, and can be expressed approximately by the first three terms of the Taylor's expansion about the point (I_o, s).

$$\phi = \phi_0 + i\frac{N\mu A}{2s} + x\frac{NI_o\mu A}{2s^2} \tag{10}$$

From equation 10 we obtain

$$\frac{d\phi}{dt} = \frac{N\mu A}{2s}\frac{di}{dt} + \frac{NI_o\mu A}{2s^2}\frac{dx}{dt} \tag{11}$$

Figure 4. Equivalent circuit of carbon pile regulator

The force due to the magnet can be expressed as a function of flux. By following the same procedure as above, a reference force value can be found and the force for different values of coil current and armature displacement found by means of an expansion.

The force due to the magnet is proportional to the square of the total flux (2ϕ) between the surfaces, and inversely proportional to the total area (approximately twice the A previously defined) through which this flux passes. Using the previously-defined symbols the force is

$$F_m = \frac{\phi^2}{\mu A} \simeq \frac{N^2(I_o+i)^2 A\mu}{4(s-x)^2} \tag{12}$$

and the reference value of the force is

$$F_{0m} = \frac{N^2 I_o^2 A\mu}{4s^2} \tag{13}$$

Then expanding equation 12 and neglecting second order terms

$$F_m = F_{0m} + i\frac{I_o N^2 A\mu}{2s^2} + x\frac{N^2 I_o^2 A\mu}{2s^3} \tag{14}$$

By substituting the expression 11 for $d\phi/dt$ in equation 1 and expression 14 for F_m in equation 5 the following equations are obtained

$$E_o + e = R_c(I_o+i) + \mu\frac{N^2 A}{2s}\frac{di}{dt} + \frac{N^2 A I_o \mu}{2s^2}\frac{dx}{dt} \tag{15}$$

$$F_{0m} - F_{0s} + F_{0p} + i\frac{I_o N^2 \mu A}{2s^2} + x\left[\frac{N^2 I_o^2 A\mu}{2s^3} - K_s - K_p\right] = M\frac{d^2x}{dt^2} \tag{16}$$

The two equations describing the regulator now have only two dependent variables, x and i, and can be solved for either one when the applied voltage $E_o + e$ is known.

To simplify the equations: eliminate $F_{0m} - F_{0s} + F_{0p}$ from equation 16 because the sum of the forces on the armature is zero when it is stationary in its reference position, eliminate the steady-state voltage and current, E_o and I_o, from equation 15 for reasons discussed previously, and let

$$L = \frac{N^2\mu A}{2s},\ U = \frac{N^2\mu A I_o}{2s^2},\ \text{and}\ K = K_s + K_p - \frac{N^2 I_o^2 \mu A}{2s^3}$$

The equations then become

$$e = R_c i + L\frac{di}{dt} + U\frac{dx}{dt} \tag{17}$$

$$Ui = M\frac{d^2x}{dt^2} + Kx \tag{18}$$

Now, since we are interested in a steady-state solution when e is sinusoidal, replace the symbol, d/dt, indicating differentiation with respect to time, with the imaginary quantity $j\omega$ where ω is the angular frequency of the applied voltage. Use bold face italic letters to symbolize variable quantities which can be interpreted as vectors and equations 17 and 18 become

$$\boldsymbol{E} = \boldsymbol{I}(R_c + j\omega L) + j\omega U\boldsymbol{X} \tag{19}$$

$$U\boldsymbol{I} = \boldsymbol{X}(K - \omega^2 M) \tag{20}$$

Figure 5. Transfer function magnitude

Only algebraic manipulation is now necessary to solve the equations for the ratio of $\boldsymbol{X}$ to $\boldsymbol{E}$. If we now multiply this ratio by P, where P is defined to be the proportionality constant between carbon pile resistance and armature displacement, we have arrived. The result is an expression for the carbon pile voltage regulator transfer function.

$$T_r = \frac{UP}{KR_c - \omega^2 R_c M + j\omega(KL + U^2 - \omega^2 LM)} \tag{21}$$

The constants of this expression are what have been referred to throughout this paper as the regulator constants. The expressions defining these constants show how they are affected by the factors entering into the design of the regulators. The defining expressions are also of value in indicating approximately how the

Figure 6. Transfer function phase

regulator constants depend on the average operating point of the regulator.

A simpler method of analyzing the regulator would have been to analyze an all electrical equivalent circuit of the regulator. By using analogies of the "mobility method" and the procedures authorized by Firestone[2] an all electrical equivalent circuit of the regulator could have been drawn and the expression for the regulator transfer function obtained from the equations describing the behavior of the equivalent system. Figure 4 is the circuit obtained by using the mobility method. The coupling between the electrical and mechanical parts is represented by a transformer with a turns ratio of U:1. The electrical equivalents of the mechanical parts of the regulator are shown to the right of the transformer in the figure. Those interested are welcome to verify the fact that the equations describing this circuit are identical to those describing the regulator when the analogies listed in Figure 4 are used. In attempting to derive the regulator transfer function expression from the equations of the electric system notice that the voltage e_2 is analogous to the velocity and not the displacement of the armature. To handle this difficulty go ahead and find the ratio of e_2 to E, then divide the result by $j\omega$ to obtain an expression for the ratio of displacement to applied voltage.

The principal usefulness of this equivalent circuit is that those familiar with electrical circuits can readily determine the qualitative effect of a proposed change in the value of a regulator constant by noting the change that would occur in the equivalent electrical circuit element. The effect of this change on the operation of the all electrical circuit can then be determined and interpreted in terms of regulator operation. The disadvantages of using the equivalent circuit for a detailed analysis of the regulator are that you do not fully appreciate what is involved in assuming the system to be linear and the usefulness of the expressions defining the regulator constants is lost.

The shape of the transfer function amplitude and phase curves are shown in Figures 5 and 6. To verify the validity of the derived expression the measurable constants of the regulator tested in the circuit previously described were evaluated and put into the expression. Values of the effective spring constant, K, the incremental operating coil inductance, L, and the coupling constant, U, which seemed reasonable but which could not be measured by known means were also put into the expression and the expression evaluated at a number of frequencies. The values of the constants used were

$R_c = 39$ ohms
$P = 327{,}000$ ohms per meter
$M = 0.059$ kilogram
$K = 76{,}600$ newtons per meter
$L = 0.145$ henry
$U = 114$ newtons per ampere

The plot of the calculated value of amplitude and phase are shown for comparison on the same figure with the corresponding measured curves.

Conclusions

The most important conclusion that can be reached from the work described in this paper is that the derived expression for the carbon pile regulator transfer function is a true expression to a high degree of accuracy. This conclusion is supported by the agreement obtained between measured and calculated values of the function. The implications of this conclusion are that the expression can be used to determine the effect on the dynamic behavior of the regulator of proposed regulator design changes and that values of the constants can be selected analytically to cause improved regulator operation.

The only conclusion to be reached concerning the circuit which was designed for measuring the regulator transfer function is that it performed its intended function. There is little doubt in the mind of the author, however, that the circuit can be used to perform numerous other useful functions. Operation of the regulator in this circuit will certainly simplify making direct studies of the effects on regulator operation of varying regulator parameters, changing the adjustment of the regulator, operating the regulator over wide ranges of temperature, pressure, and humidity conditions, and operating the regulator while it is being subjected to vibration.

Of course, the effects of the regulator operating characteristics on the dynamic characteristics of the entire voltage regulated electric system must be determined before evaluation of the factors affecting regulator operation is worthwhile. This becomes a relatively simple matter, though, when the analytical method involving the use of transfer functions, which was mentioned earlier in this paper, is used. The author therefore suspects that the most significant contribution of this paper to the field of analyzing electric systems regulated by variable resistance devices may turn out to be the pointing out of the fact that the "figure of merit" of the regulator, its transfer function, should be defined as the ratio of resistance variation to operating voltage variation.

Discussion

K. W. Carlson and **E. S. Sherrard** (General Electric Company, Schenectady, N.Y.): The author is to be complimented on a valuable and timely paper. An accurate representation of the aircraft carbon-pile regulator is very important when considering the stability of an electric system. The analysis by the author has resulted in a good representation with the exception of a few points which we believe are necessary to include.

In his analysis the author considers an ideal regulator without friction in the carbon pile. However, on the same type of carbon pile regulator we have found it necessary to consider friction effects on the transfer function of the regulator. If one assumes that friction is a function of velocity and linearizes the system, equation 18 becomes:

$$Ui = M\frac{d^2X}{dt^2} + F\frac{dX}{dt} + KX$$

and equation 21 becomes:

$$Tr = \frac{UP}{KR_c - \omega^2(R_cM + FL) + j\omega(KL + U^2 + R_cF - \omega^2LM)}$$

where F is the friction coefficient of the carbon pile. For typical values of the constants friction may be neglected except in the coefficient of the ω^2 term. Its principal effect on the transfer function is to increase the phase shift at low frequencies, decrease the slope of the phase shift curve in the region of resonant frequency, and lower the peak of the transfer function magnitude at the same resonant frequency.

Another departure from an ideal regulator involves the iron losses of the regulator. A plot of the ratio of voltage to current of the regulator coil versus frequency will show that the ideal equations do not accurately represent the regulator. This effect possibly may be approximated by the introduction of a shorted turn linked magnetically with the voltage coil.

R. L. Mills: I am grateful for the comments of Mr. Carlson and Mr. Sherrard on my paper and I find their opinions concern-

ing pile friction particularly interesting. I regret that they did not go into more detail on how they came to the conclusion that the term needed for improving the accuracy of the transfer function expression appears when pile friction is considered. In trying to picture pile friction in my mind I visualize particles on the surfaces of adjacent carbon disks sliding against one another as pile pressure is varied. I am skeptical of forces resulting from such friction being proportional to velocity and of them being of appreciable magnitude. Therefore I wonder if an equivalent term might not appear in the expression if some other factors neglected in the analysis were considered. Iron losses, for example, which were mentioned by Carlson and Sherrard unquestionably exist and proper consideration of their effect may also give rise to the desired term. In this case the existence of appreciable pile friction would certainly be open to question.

These discussions serve to emphasize the point that much is still to be learned and explained about the behavior of the carbon pile regulator. I admit that many factors affecting the operation of the device were neglected in this first reported study of the dynamic characteristics. It is to be hoped that these other factors will be considered in future studies so that regulator design can be more easily improved, but I feel that further refinements in the regulator analysis are unnecessary for reasonably accurate analyses of the systems in which the regulator is used.

Wide Speed Range A-C Electric Systems for Aircraft

Synopsis: The increased demand for variable-frequency a-c generating systems on present-day aircraft calls for the development of adequate generators and their controls in order that the advantages of these systems may be fully realized. The requirements are good voltage regulation, exciter stability over the required speed range, and general reliability in operation under the various environmental conditions experienced in military aircraft service. Several such generators and their controls have been developed and tested.

WITHIN the past few years there has been a noticeable movement on the part of the military services and the aircraft manufacturers toward the use of variable-frequency electric power for use on newer airplanes. This movement has resulted in the need for a-c generators which can be mounted directly on an engine accessory pad and be driven at speeds proportional to those of the main engines. This has meant that speed changes of as much as 2-to-1 must be covered in the rated speed range of the alternator.

Extensive work has been done in the past on the development of constant-frequency generating systems for aircraft use and is adequately covered by other authors.[1,2,3] The main incentive for the use of the variable-frequency system over the constant-frequency system is the elimination of the variable-ratio, constant-speed drive between the main engine and the power take-off to the generator shaft. Constant speed drives are not highly efficient and their weights approach that of the alternators which they are to drive.

The higher efficiency and lower weight of the variable-frequency generating system is especially attractive to the military aircraft industry and within the past few years more and more applications have been made of this type of electric power supply. It has long been recognized[4] that such a system has an inherent disadvantage in that it is not suitable for induction motor loads. Electronic, lighting, and heating loads can be served adequately, but the torque and speed of induction motors changes with frequency. However, the majority of the applications for this type of electric power are radar and other electronic loads, deicing equipment, and various heaters of all types.

Actually, the use of variable-frequency power on aircraft is not an entirely new idea, but in the past most of these systems were either bus-excited from the conventional 28-volt d-c system or were self-excited by means of electronic exciters.[5] The important change to be considered here is the use of an integral exciter, mounted on the same shaft as the rotating field of the alternator. In the past the design and development of such a direct-connected integral exciter was a factor which made the use of such an excitation system very difficult.

This paper will cover specifically the design and development of a 30-kva, 0.9 power factor, 3-phase 208/120-volt 4,000-/8,000-rpm alternator and the controls necessary for proper operation. The major portion of the paper will be devoted to the discussion of this system. Mention will be made of one other similar system.

General Description

Alternator and Exciter

Figure 1 shows a cross-sectional drawing of the 30-kva alternator. The a-c generator is a salient pole machine which provides a frequency of 600 cycles per second at the nominal speed of 6,000 rpm. A rotating field is used with damper windings to improve the wave form and limit the degree of phase voltage unbalance for unbalanced loads.

The exciter is a 6-pole machine with pole-face winding and a full set of interpoles. Compensation against armature reaction is essential to obtain good commutation and to reduce compounding effects from the conductors undergoing commutation.

The a-c generator and exciter are mounted on the same shaft which is supported between two bearings. The rotor is built to withstand an overspeed of 11,000 rpm giving a peripheral velocity of 20,800 feet per minute. To withstand the high centrifugal forces, the rotating field magnetic structure was made by stacking punchings on a tubular shaft. Each punching is an incremental part of the 12 salient poles and the yoke. This construction necessitated winding the coils directly upon the punchings since individual poles are not removable.

An internal fan attached to the rotor provides ventilating air while the airplane is on the ground and there is no ram air pressure. This gives sufficient cooling for the alternator to deliver 25 per cent rated load. Figure 2 illustrates the unit.

Voltage Regulator

Alternator voltage regulation is accomplished by controlling the exciter which supplies the power directly to the alternator field. A carbon-pile regulator provides a variable resistance in series with the shunt field. This resistance is changed in accordance with the particular speed and load conditions to maintain a constant alternator output voltage.

A conventional voltage sensing circuit

Paper 50-276, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3-5, 1950. Manuscript submitted July 11, 1950; made available for printing August 30, 1950.

is used as shown in Figure 3. Open-delta-connected transformers and a 3-phase full-wave bridge rectifier supply the signal to the regulator coil circuit. This particular transformer connection is lighter and less bulky than a 3-phase delta or Y connection. The signal is an average of the three line voltages, and has the advantage of holding all line voltages near an average value, when unbalanced loads are imposed upon the alternator; then the third harmonics and others which exist when sensing a single line to neutral voltage, are cancelled. The open-delta-connected transformers are designed for the minimum frequency encountered, because the maximum flux density in the core and the maximum core losses occur at this frequency for a constant voltage input.[6] Tests have shown that the effect of frequency over the range involved is negligible so far as it concerns the sensing circuit of the regulator.

The carbon-pile regulator is similar to conventional d-c generator voltage regulators.[7,8] It is a self-contained unit which, when properly adjusted, will operate to maintain the generator output voltage within 2 to 3 per cent if the operating range for which the system is designed is not exceeded. Alternator speed and load changes, result in momentary changes in the generated voltage, which are received as signals at the regulating coil of the carbon-pile regulator. This produces a change in the coil magnetizing force which, in turn, ~~acts on the~~ armature of the magnet to oppose the force exerted on the carbon pile by the armature spring. The pressure change on the carbon pile is sufficient to change its resistance so that the exciter field current will assume the required value to allow the alternator to again generate the desired voltage.

In order to co-ordinate the design of an alternator and a regulator certain factors concerning the limitations of the carbon pile must be considered.

The particular force-deflection characteristic of the carbon pile and its relationship to the magnet pull curves and armature spring characteristic[9] demand that the ratio of maximum to minimum external exciter shunt field resistance should not exceed approximately 30-to-1. If a resistance ratio greater than 30-to-1 is required, due to the particular exciter de-

sign and load demand, difficulty is likely to be encountered at either or both ends of the resistance range.

For example, at the lower end of the resistance range an increasingly greater droop in voltage may be required to produce the force necessary on the carbon pile to obtain this resistance. At the higher end of the resistance range the force required may be so small that the regulator is susceptible to vibration and acceleration.

Experience indicates that for most applications the average voltage per carbon disk in the pile should not exceed a maximum of one-half volt. If this value is exceeded an arcing condition results which is much like that encountered in instability of mechanical vibration conditions. This maximum value of voltage per disk can be exceeded slightly but only at the expense of the resistance range.

The maximum wattage dissipated in the carbon pile is another important consideration. The designer of the alternator and exciter should bear in mind that any regulator has definite maximum heat dissipating capacity and this value should not be exceeded, except for possible short time intervals. The maximum power in the regulator at any output voltage of a shunt exciter is expressed as.[10]

$$P_{max} = \frac{V^2}{4R_F}$$

where

P_{max} = maximum power, watts
V = exciter output volts
R_F = exciter field resistance, ohms

Consideration also should be given to altitude conditions particularly with respect to the possibility of the regulator overheating. Higher wattage capacity has been obtained by using more than one standard regulator, but this adds to the problem of adjustment and maintenance, both of which are important factors to the successful design of any electric power system.

An anticipating transformer is used to stabilize the excitation system under transient load conditions. This transformer introduces a signal into the regulator coil circuit in series with the signal from the main voltage sensing rectifier. This feedback signal is of such a polarity as to oppose the original change and is proportional to the rate of change of the exciter output voltage. The effect of this stabilization tends to prevent over or under shooting the correct value of the excitation for the new load condition. Theoretically, the direct current flowing in the primary and secondary windings of the transformer should cancel each other preventing saturation in the transformer core. Actually this condition cannot be obtained except for a particular exciter output voltage, because the primary of the transformer is directly connected across the exciter, while the secondary is in series in the regulator coil circuit which carries essentially constant current. For this reason an air gap is purposely introduced into the magnetic core in order to obtain the maximum possible incremental permeability over the range of operation of the system.

The regulator circuit is temperature compensated by means of the inverse-temperature-resistance characteristic of two special carbon resistors and the selenium rectifier cells. Tests have demonstrated that the voltage regulation is between 3 and 4 per cent over the temperature range of −55 and +71 degrees centigrade.

Figure 4 shows a view of the regulator completely assembled, and also shows the same regulator with the carbon pile element removed and the cover and end plate removed from the box assembly.

General Theory

An excitation system for a constant-frequency alternator will be discussed first since the scheme to be discussed later has many points in common with this system. Figure 3 indicates the essential parts of the system under consideration.

The operation of the exciter and its required regulator resistance range can be studied by the aid of curves given in Figure 5.

The shunt field line, voltage versus current, can be drawn in as a straight line assuming that its resistance is constant at a particular temperature condition. On the load saturation curve "OD" at any particular value of exciter output voltage, V, there is a corresponding field current, I_F, a voltage across the regulator stack,

Figure 6 (below). Curves of separately-excited exciter and various amounts of external resistance. See schematic diagram Figure 10

Figure 5 (left). Load saturation curves at maximum and minimum speed of a shunt exciter with resistance lines for the shunt field and various amounts of external resistance

V_S, and a voltage across the field, V_F. The stack resistance is then simply V_S/I_F. Different values of stack resistance can be readily calculated and plotted as indicated by the resistance curve in Figure 5. It is apparent that if the resistance curve should have zero slope or positive slope at any point there could exist more than one value of output voltage for a given regulator stack resistance. This will cause the exciter to be very unstable and result in the output voltage of the alternator being modulated at a frequency corresponding to the regulator stack movements.

Another way of arriving at the stack resistance, amounting to the same thing but somewhat more explicit, is to draw in a number of resistance lines intersecting the load saturation curve at various points such as the lines *OA*, *OB*, and *OC*. Each of these lines represents the shunt-field plus a certain amount of stack resistance. In regard to stability with this method of analysis, the saturation curve resistance must not coincide with any resistance line of the exciter, nor can there be any resistance line that intersects the load saturation curve at more than one point if the exciter is to be stable.

The degree of stability of the exciter is indicated by the magnitude of the angle between a resistance line and the saturation curve.[11] This is apparent by observing that as this angle becomes small, a very small change in stack resistance produces a great change in the exciter output voltage. Restating this principle in other words, the intersection angle between the two lines must always be greater than zero.[12]

Considering a wide-speed-range alternator of 2-to-1 speed range, such as the 30-kva alternator described, the problem is greatly complicated in attempting to fulfill the requirements previously mentioned. The same remarks must apply for all speeds within the rating of the machine, or an infinite number of saturation curves. For instance, the saturation curve, "OD," may be for minimum speed, and the curve "OE" for maximum speed. It can be assumed that at high speed the flux density in the air gap and the main magnetic circuit is very low. For this reason, the lower portion of the load saturation curve is practically a straight line. Fortunately, there is a small amount of residual magnetism in the magnetic structure which causes the exciter to have a few volts output with zero field current. This makes it possible to draw a straight line from the origin and intersect this load saturation curve such as resistance line *OF*. Here

Figure 7. 30-kva aircraft alternator field requirements at various loads

(Left)—field amperes versus alternator speed
(Right)—field voltage versus alternator speed
(includes slip ring brush drop)

the angle of intersection becomes very small, and if it were not for excellent performance from the carbon pile regulator and the stabilizing circuit, very likely the speed range would have to be reduced for satisfactory operation.

When a separately-excited exciter is used, the problem is simplified in several respects. Here the regulator stack resistance is not influenced by the exciter output voltage, see Figure 6. As before, the stack resistance is equal to the value of the resistance line, such as R_1 or R_3, less the field resistance for any particular values of field current. For any desired value of the exciter output voltage, a set of load saturation curves will be required.

The time constants of the exciter field, the alternator field and the exciter armature are important considerations in a study of the stability of an a-c generating system. It is beyond the scope of this paper to discuss these constants and reference is made to R. E. Doherty's authoritative paper Exciter Instability.[11] This paper also deals with exciter polarity reversals, a difficulty which is encountered on aircraft application of exciters.

Test Results

Curves of the voltage-current requirements for this alternator are shown in Figure 7 and cover the entire speed range at different loads. The first unit built and tested gave a load saturation curve at 5,000 rpm as roughly shown in Figure 8, curve "A." For different speeds, giving different saturation curves, the slight dip near the origin approximately held its position. Since the trouble occurred mostly at high speeds, it appeared that the regulator could not operate satisfactorily with such small amounts of field current, because minute changes in the field current resulted in very large changes in alternator output voltage. It was then recognized, however, that the problem became one of "shaping" the load saturation curves so that the ratio of the stack voltage to the field current always decreased with an increase in the output voltage of the exciter.

It was theorized that the dip in curve "A," near the origin was a result of the compounding effect from the conductors undergoing commutation. This was not enough, however, to account for the dip in the curve. Changing of the interpole face and adjusting the interpole ampere-turn strength resulted only in a slight shifting of the position of the dip.

Realizing the difficulty in correcting the compounding effect, the problem was approached by placing shims under the main poles, the thought being that the shims would begin to saturate at the point of dip in the curve. Above that point the thickness of the shim would be virtually the equivalent to an air gap added to the magnetic circuit of a length equal to the thickness of the shims. Results were somewhat encouraging, but the dip still remained to the extent that the machine would not regulate with the carbon pile regulator.

Since the air gap between the pole tips was relatively small, the leakage flux from the tips of the interpoles to the main poles was blamed for saturating the interpole tips. It was decided to increase the compensating windings from 50 to 100 per cent compensation to cut down the magnetomotive force between the trailing edge of the main poles and the interpole. The change, it was thought, would result in a more nearly ideal flux distribution under the interpoles. In addition, a careful calculation was made for the design of the shims under the main poles, and it was decided to use two 0.014-thick by 0.100-inch wide shims which ran the length of the pole, one on each side of the pole centerline. Previously, 0.002-inch and 0.005-inch thick shims had been used.

Figure 8 (left). Typical curves of shunt exciter showing effect of modifications in design

A—Original design
B—Compensation increased to 100 per cent and shims added to magnetic circuit
C—Main pole tips ground to decrease leakage to the interpoles

Figure 10 (above). Schematic diagram of 60-kva aircraft a-c electric system showing separately-excited exciter

The material selected was carbon steel shim stock.

Test results gave a curve as shown in Figure 8, curve "B." This was an improvement over previous attempts, but there was still a slight dip in the curve. The regulator worked to a degree at all speeds but there was a slight modulation of the output voltage when the exciter was operating on the dip part of the curve at some speeds. At most speeds it was satisfactory, but when the conditions of load and speed were reached such that the ratio of the stack voltage to the exciter field current was a constant, the trouble occurred.

The last trial gave satisfactory results. The output of the exciter was more than ample to supply the alternator, so it was decided that the output could be lowered a slight amount and permit grinding off the main pole tips to further decrease the leakage to the interpoles. The pole arc was reduced from approximately 67 per cent of the pole pitch to 60 per cent. Tests on this unit gave data which resulted in a curve shaped as shown in Figure 8, curve "C." There were no dips or straight portions on any part of the curve except at the very low voltages below minimum operating point. The regulator controlled the voltage over the speed range from no-load to full-load with the allowed $2^1/_2$ per cent regulation.

Curves for the final exciter as described are given in Figure 9. Resistance lines are drawn in to readily give the regulator stack resistance values. It is to be noted that the maximum resistance of the field circuit is 18 ohms at 10,000 rpm, no-load, and the minimum is 5.5 ohms at 4,000 rpm, 150 per cent load. A requirement of the applicable government specification was that the voltage should be controlled from 8,000 to 10,000 rpm at no load. Subtracting the field resistance of 4 ohms gives a regulator stack resistance of 14 ohms and 1.5 ohms for the two conditions which are well within the required 30-to-1 resistance ratio.

Other Systems for Wide Speed Application

There is a program of development at the present time on a 60-kva a-c generator and control system which incorporates the use of a pilot exciter to supply the main exciter field, thus eliminating the trouble encountered in "shaping" the main exciter load saturation curve. This additional exciter is regulated to a constant voltage of 35 volts by a separate carbon pile regulator. This constant voltage provides excitation to the main exciter field. A second carbon pile regulator serves to adjust the main exciter field current, by means of a circuit the same as that described for the 30-kva machine. Figure 10 shows this system. An additional feature which contributes to the stability of the system is the differential field on the main exciter. This field, excited from the constant voltage of the pilot exciter, gives a magnetizing force which opposes that of the main exciter field windings. Thus, the zero-output voltage point of the main exciter is at some field current value which provides just sufficient ampere turns to balance those of the differential field. This effectively lowers the resistance range required of the main regulator stack by reducing maximum required resistance.

Conclusions

The self-excited exciter electric power system appears to be the most advantageous from the point of simplicity and weight, because there is a minimum of auxiliary controls necessary for its proper operation. However, there is considerable difficulty in properly adjusting the exciter to provide the suitable type of load saturation curve desired. Differences in commutator films and commutation qualities, coupled with unavoidable brush movements at high speeds, indicates that some other solution to the problem is to be desired.

The pilot exciter and main exciter electric power system is inherently more stable than one without a pilot exciter, and it eliminates the danger of polarity reversals. The recovery time of the system would be shorter than that of a system without a pilot exciter because of the constant voltage available for supplying the main exciter field.

Discussion

K. W. Carlson and **E. S. Sherrard** (General Electric Company, Schenectady, N. Y.): The authors are to be complimented on their lucid description of an a-c aircraft electric system. However, several points of the sections on General Theory and Conclusions need discussion.

In the section on general theory the statement is made that if the system is to be stable the angle θ must be positive. θ is the angle at the operating point between the slope of the exciter saturation curve and the field circuit resistance line. A method is described for insuring the positive value of θ by shaping the exciter saturation curve.

It should be noted that an AIEE paper[1] in 1939 conclusively shows that systems of this type may be stable even when θ is negative. In particular, a large margin of stability may be obtained for $\theta = 0$ or slightly negative.

If the saturation curve is shaped the weight of the machine is normally increased and regulator sensitivity also must be increased to maintain the same system performance. The shaped saturation curve may change with commutator film, brush wear, and overhauls by users.

We suggest that a stability analysis would show that stability can be obtained by more reliable methods than the shaping of exciter characteristics.

In the conclusions a pilot exciter system is suggested for future systems. This will introduce into the system a third machine, a third set of brushes, and a second carbon pile regulator. The resultant system could be expected to be heavier and also would afford more opportunities for failure or malfunctioning of the system. We believe a pilot exciter system could be less reliable than a simpler single exciter system. Reliable methods of stabilizing these simpler systems can be determined by stability analyses.

H. B. James, R. P. Judkins, and **C. L. Mershon:** Mr. Carlson and Mr. Sherrard refer the authors to an AIEE Paper, published in 1940 which covers the case of a "negative angle" between the exciter saturation curve and the field circuit resistance line.

The stability boundary, in this paper, is found by applying Routh's criterion. It is shown that Routh's criterion may be satisfied if the slope of the exciter saturation curve is greater than the slope of the resistance line, both being taken at the operating point, provided that there is a suitable feedback transformer. If Routh's criterion is in fact met then the system response to either a unit step or a unit impulse in alternator output voltage will consist of decaying oscillations or exponentials, or combinations of these. Since the response to any other disturbance may be found by a simple integration the system is considered stable.

Should the angle θ discussed in the paper be negative, and if the regulator stack resistance starts to increase say according to $R(t) = R_o + Kt$, then it is readily shown by elementary mathematics that the shunt field current (and with it the exciter output voltage) begins to increase. If now a sufficiently large rate signal is applied to the regulator, its stack resistance will increase so rapidly that the shunt field current transient is arrested, and the system is stable.

In the case of a unit impulse or unit step in alternator output voltage, the initial rate signal applied to the regulator coil is a well-defined number, and the subsequent oscillations in shunt field current may be calculated. The system response may be compared with established standards for acceptable performance.

However, disturbances other than unit steps or unit impulses may be encountered. Although the response to any other disturbance will be "stable" in the mathematical sense, that is, the oscillations or exponentials in the response will decay, this does not guarantee that the changes in the system variables will remain within the range of linearity. For example, if the regulator stack resistance should increase slowly, with θ negative, the amount of rate signal is much reduced. The shunt field current is then free to increase to a high value before adequate regulator action takes place. Whether the regulator is able to regain control depends upon the degree of nonlinearity and the amount of rate signal. Situations of this kind, which tend toward instability, may be eliminated if θ is made greater than or equal to zero.

The particular system under consideration operates over a wide speed range, resulting in excitation changes over the full range of approximately 8 to 1 (see Figure 9). In order to provide stable operation of the system under this variable voltage condition, air gaps are placed in the magnetic circuit of the anticipating transformer which result in an increase in weight of this component to provide the proper amount of mutual inductance for stable operation. If the additional condition of a negative angle, θ, be imposed, this adds further to the weight of the transformer, and as pointed out before even this may not be adequate to provide a stable system due to deviation from the idealized case of linearity of the various system parameters. This deviation of parameters is always much more severe in the case of aircraft applications due to ambient conditions and operating characteristics far more severe than those encountered in central station practice.

Concluding, it should be emphasized that in spite of the mathematical validity of stable conditions in the presence of a negative angle between the exciter saturation curve and the field circuit resistance line, the more practical considerations which prevail in this type of application indicate that the criterion of a zero or positive angle is definitely necessary if a practical solution is to be attained.

Aircraft Electric Motors Need Test Equipment

I. E. ROSS
MEMBER AIEE

ALERT manufacturers of electric devices for aircraft must continually analyze their ability to conceive, evaluate, and produce in adequate quantities new equipment to meet the everchanging performance needs of civil and military aviation. This statement is especially true of companies which may feel the major manufacturing impact of various X-group Air Force programs authorized by Congress.

An important segment of the large problem is the matter of equipment performance evaluation. In recent months this phase of designing for aircraft has been rendered increasingly difficult both by the complexity of current environmental requirements and tests, and by continued assault upon the limits of the operating arena. Test equipment, painstakingly and ingeniously designed to simulate specified operating conditions, may often become obsolete in the time consumed by the drafting, development procurement, and installation cycle.

This paper is a discussion of one manufacturer's program to provide a test facility for evaluating rotating electric equipment not exceeding 100 pounds in weight, and over-all dimensions of 30 by 10 by 15 inches, and having d-c or a-c power dissipation of 5 kw.

The program required two years to complete at an actual expenditure in excess of $160,000 for only the four types of equipment discussed. When equipment to administer specified tests for humidity, fungus, explosion-resistance, sand and dust, salt spray, and sea level cold must also be purchased, the outlay in time and money is appreciably greater.

Analysis of this manufacturer's problem revealed that equipment was needed to meet existing specifications of acceleration, altitude, low temperature, mechanical shock, and vibration. In some cases, equipment already available was obsolete, failing to meet revised requirements. In other instances it was of inadequate physical or thermal capacity. Engineers were assigned the responsibility of obtaining, either by purchase or by manufacture, a group of indicative testing machines. The project was subdivided into several phases as follows:

1. Analysis of currently applicable military specifications to establish immediate testing goals.
2. Selection, through discussion with official aeronautical groups, of goals sufficiently beyond existing requirements to insure utility of the equipment when actually put into service. Final decision on this point was a compromise between the fruits and the costs of foresight.
3. Examination of appropriate equipment both within and without the company, on the premises of other industrial organizations or among the laboratories of the Armed Forces.
4. Choice between purchasing or building the desired machines.

Discussion of the program as it was applied to the several pieces of equipment will generally follow this outline.

Acceleration

In specifications *AN-M-40*[1] and *AN-I-10b*[2] are found requirements for acceleration tests on two types of rotating equipment, d-c motors and inverters. Motors must "start and run satisfactorily" while "mounted on a centrifuge" "operated at a speed that will produce an acceleration of ten gravitational units." The test is made for six positions of the motor. Inverters are required to withstand the force, in each of six axial directions, of five gravitational units. Under this test, a maximum deviation of 3 per cent in controlled voltage and frequency is allowed at full load and at no load. An earlier United States Air Force-32590,[3] requires a test of 12 gravitational units.

The United States Air Force General Specification for Environmental Test of Equipment, Number 41005-B,[4] stipulates that test equipment must be capable of administering steady accelerations up to 20 *g*'s.*

It is significant that acceleration requirements are not encountered in all specifications. The indication is that the test is not of universal importance. Investigation of this point with representatives of one of the Services, however, revealed an opinion that acceleration performance to them is more important than operation through short-duration shocks. At the recommendation of this group, a design bogey of 100 g was established for a new centrifuge.

No equipment suitable for the testing of rotating machines was discovered within the company or within the laboratories at Wright Field or the Naval Research Laboratory. Accordingly, it was necessary to develop a new device.

Centrifuge Design

The new centrifuge, Figure 1, is designed to carry a load of 400 pounds distributed thus:

	Pounds
Test piece	100
Mounting	100
Counterbalance†	200

† May be a second test piece and mounting.

Maximum acceleration of 103 *g* is obtained at 450 rpm and a radius of 18 inches. In construction, the centrifuge is a 4-foot diameter steel table out of which

* *g*—acceleration of 32.2 feet per second per second.

Paper 50-277, recommended by the AIEE Air Transportation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Middle Eastern District Meeting, Baltimore, Md., October 3–5, 1950. Manuscript submitted July 14, 1950; made available for printing August 28, 1950.

I. E. Ross is with the General Electric Company, Fort Wayne, Ind.

Figure 1 (left). 100-g centrifuge

Figure 2 (right). Standard temperature-altitude chart, Specification AN-M-40

rises a 12-inch square shaft. Provision is made for mounting test pieces on the flange and on the sides of the shaft, if desired.

The drive is a 15-horsepower d-c motor utilizing automatic speed control. Interlocks are provided to prevent accidental operation of the machine when test motors are being assembled or removed. The control circuits can be arranged for dynamic braking or plugging to obtain rapid stopping. Preliminary tests indicate that the plugging circuit will not be necessary. The motor will bring the fully loaded centrifuge up to 450 rpm in approximately 10 seconds.

Power to operate the units under test is provided through 14 slip rings located at the top of the machine. That number is considered adequate not only for power but for instrument or thermocouple leads as well.

The entire machine is surrounded by a shell of 3/4-inch steel plate to protect operating personnel in case of a failure of mounting or motor.

Altitude and Low Temperature

Applicable Air Force-Navy specifications in effect at the opening of this program require operation up to 50,000 feet at a temperature of −55 degrees centigrade. The generally accepted temperature-altitude combination is as shown in Figure 2, taken directly from specification *AN-M-40*.[1]

United States Air Force specification 41065B[4] suggests that apparatus for altitude testing should be capable of holding 85,000 feet and an internal ambient temperature of −65 degrees centigrade. It further requires that the dew point of internal air be controllable between zero and −80 degrees centigrade. A warning is added that no grease, oil, or other impurities shall be present within the evacuated space. Another reference to quality of the air is found in an earlier specification, AN-M-10a,[5] where a dew point of −50 to −80 degrees centigrade is specified.

The careful design and construction of a good altitude chamber can take 12 to 18 months. In these days, with ceilings continually rising and unexpectedly low temperatures being recorded, it is difficult to decide what performance will be needed two years hence. Altitudes of 60,000 and 80,000 feet are already being specified. Horizons of 200,000 feet are mentioned for sustained flight. Temperatures of −85 degrees centigrade in conjunction with high altitude are being reported.

Furthermore, the difficulty of design and the cost in time and money of chamber construction increase cumulatively as altitudes become higher and colder. Even at altitudes under 100,000 feet, heat dissipation by convection is practically nil, and refrigerating plate areas increase by leaps and bounds. At the same time, the lower temperature levels tax the capabilities of simple refrigerating systems using normal refrigerants.

Under these circumstances the problem of setting practicable design parameters was a difficult one.

Figure 3 shows the predicted performance of the chamber which became the final design after most of the elements of compromise had been considered. For light thermal loads, an ambient temperature of −45 degrees centigrade will be available at 100,000 feet. The chamber was designed to dissipate 3 kw plus internal fan and lighting losses at −65 degrees centigrade and 60,000 feet. Minimum cold temperature at low altitudes of −75 degrees centigrade is predicted.

Investigation of numerous altitude chambers throughout the eastern part of the country revealed none which was completely suitable. A 90,000-foot chamber at Wright Field had no refrigeration. An 80,000-foot chamber in the Lynn River Works of the General Electric Company was too large, having been designed for engine testing. Another 80,000-foot tank at Wright Field was without humidity control. The chamber most closely resembling the needs of the program was located in the Naval Research Laboratory in Anacostia, Md. Rated at 70,000 feet, −60 degrees centigrade and equipped for

Figure 3. Altitude chamber performance

admitting clean dry air, it included humidity control down to −60 degrees centigrade dew point.

It was decided to design a new chamber. The parts would be purchased wherever approved components could be found, and the entire chamber and auxiliary devices would be assembled on the manufacturer's premises.

Altitude Chamber Design

Mechanical

The structural backbone of the chamber is a 10-foot diameter reinforced steel horizontal cylinder 3/8-inch thick, and about 15 feet long. Centrally fixed within this piece is a second cylinder made of stainless steel and having an inside diameter and length of 8 feet by 13 feet 6 inches, Figure 4. The 7 feet to the rear of this space, separated by a bulkhead, enclose cooling coils and internal circulating fan. The remainder is arranged to provide 50 square feet of workspace. A rectangular door 74 inches by 30 inches, mounted on the front end of the tank provides physical access to the interior.

The space between the two cylinders contains reflector-type insulation of stainless steel. There are 17 layers of 0.005-inch sheets located on 1/2-inch centers provided with breather holes between layers to permit evacuation of the entire assembly without distortion of the insulation structure. A window is provided on each side of the chamber, enabling operators to observe tests in progress.

It is an almost universally accepted fact that the keynote in reliable altitude chamber performance is cleanliness and dryness of the ambient air. This characteristic of chamber operation reflects itself in design at least at five points.

1. The interior must be free from materials which retain moisture vapor or other contaminants. Finishes or materials having a vapor pressure of their own must be avoided.

2. The evacuation and through ventilation system must handle only dry clean air.

3. There must be provision for purging the chamber with quantities of dry clean air at the beginning of tests.

4. Interior ventilating and refrigerating systems must remove dust and vapor contaminants from circulating air.

5. Leakage of all kinds must be kept to an absolute minimum.

Vacuum System

Evacuation of the new chamber is accomplished by a 750-cubic-feet-per-minute vacuum pump driven by a 40-horsepower motor. Specified pull-down time to an interior pressure of 8 millimeters of mercury (100,000 feet altitude) is six minutes. An altitude condition of 60,000 feet can be obtained in 3 minutes. Bleed-in air is taken from the factory compressed air line at 25 degrees centigrade, 90 pounds per square inch, Figure 5. It is passed through filters and refrigerated to +5 degrees centigrade to remove contamination and much of the moisture vapor. An activated alumina drier removes most of the remaining water vapor and delivers approximately 90 pound-per-square-inch air having a dew point of −80 degrees centigrade and a temperature of +10 degrees centigrade to an expansion valve located just outside the chamber. At this point provision is made for sampling the air and measuring the dew point. The cooled, cleaned air is allowed to expand through a second cooling coil, located in the internal refrigerated circulating air stream, into the front section of the chamber. A flexible tube is provided so that incoming air can be directed to any desired spot within the work area.

At sea level pressures, 300 cubic feet of prepared air per minute can be drawn in and circulated through the tank for purging purposes. This value represents about one complete air change every two minutes in the inner tank. At an altitude of 60,000 feet the vacuum pump capacity of 750 cubic feet per minute will draw about 75 cubic feet of purified sea level air into the chamber each minute. At 100,000 feet the per-minute bleed-in volume is nearly 10 cubic feet of atmospheric air. Both of these conditions represent a complete air change every minute within the tank.

Figure 5. Altitude chamber ventilation system including preparation in-bled air

The suction pipe to the vacuum pump draws air directly from the work space. Like the bleed-in line, the exhaust can be fitted with a flexible tube if it is desired to withdraw air from any specific portion of the test area. The low-pressure air is filtered before reaching the pump to prevent damage to that component from excessive contamination and carbon dust. Automatic altitude control is provided by means of by-passing clean air from the outlet of the alumina drier (or the high-pressure filter) to the inlet of the continuously running vacuum pump. The device which controls this operation also records the internal pressure.

Refrigeration

Low temperatures inside the chamber are developed by a 2-stage mechanical refrigeration system using Freon-22 gas. Three 40-horsepower 1,750-rpm motors drive 8-cylinder 600-rpm compressors of which two cylinders each are high pressure, or second stage, and six cylinders are low pressure. Part of the refrigerant is delivered, through a heat exchanger and a supercooler, to the low-temperature coils in the rear section of the chamber. The remainder is directed through coils on the walls of the inner cylinder to provide a cold-wall barrier to thermal leakage through the insulation. The walls and

Figure 4. Altitude chamber layout

the coil surfaces represent 10,000 square feet of heat-absorbing area. They are designed to remove 47,000 Btu per hour at 60,000 feet altitude and −55 degrees centigrade from the test load, 100 watts of lighting, and approximately 2 kw of circulating fan motor power, plus thermal leakage losses. At sea level, pull-down time from room temperature to design temperature is approximately 4 hours.

Temperature of the ambient air is maintained at desired values by a resistance-type, recording, controlling thermometer. Another instrument can record readings from 16 pick-ups distributed about the chamber, on walls, on test piece, on fan motor or wherever such data should be collected. Specially designed resistance pickup points, housed in small stainless steel bulbs and shielded from radiation, are used as sensing elements.

Of interest in connection with the low-temperature tests is the provision inside the chamber of electric heating elements. These units are to be used at the conclusion of a cold test to return the chamber to room temperature before it is opened to a moist warm atmosphere. This step will prevent the voluminous condensation of water which would otherwise take place.

Recirculation

The treatment of circulating air is carefully worked out to limit cumulative contamination as tests of long duration progress. Inside air is drawn along the walls, over the refrigerating coils, and past the inbled air cooler by a 36-inch vane-axial fan mounted in the top half of the top half of the bulkhead which divides the chamber. The output is delivered directly to the front section above the work. The table tops and the floor are plated steel gratings which provide for easy mounting of test units and allow the circulating air to pass down to its return area below the floor level. Directly beneath the steel gratings are 300 activated charcoal filters, arranged to pass all the circulating air. Mounted in sections, and on racks, they can be removed easily for cleaning or replacement. It is felt that the filters, plus the cold coils, will render recirculated air satisfactorily free from contamination.

The circulating fan is powered by a 3-phase 60-cycle 4-pole motor rated three horsepower. It is of totally-enclosed ball-bearing construction and draws power from a variable-voltage variable-frequency motor-generator set. The rating of the fan is 25,000 cubic feet per minute at 1,660 rpm of air having 0.097 specific gravity (approximately 80,000 feet) and dissipates at that point 2.2 horsepower. At sea level, the fan is rated 5,000 cubic feet per minute and draws 0.4 horsepower at 400 rpm. The motor-generator delivers power over a frequency range of 13 to 60 cycles to match the fan requirements.

Figure 6. Standard "light-weight" Navy impact machine

Mechanical Shock

Specifications *AN-M-40*[1] and *AN-I-10b*[3] require d-c motors and inverters to withstand 60 shocks, ten in each direction along the three axes. The value of the shock is specified as "10 g". An earlier United States Air Force specification 71-854[6] called for 10 shocks of 25 g intensity.

United States Air Force specification 41065B[4] reads:

"The apparatus shall consist of a device.... for mounting and giving linear acceleration to components through the following ranges:

175 g at a time duration of 0.003 second
40 g at a time duration of 0.010 second
15 g at a time duration of 0.015 second

The first issue of AN-E-19[7] included a specification for shock which reads as follows:

"The equipment.....shall be designed so that no damage or maladjustment shall result from 25 cycles of the following: Maximum acceleration, applied in any direction of 8 g (257 feet per second per second) developed at a constant rate in 0.1 second and sustained for 3 seconds and the same acceleration developed at a constant rate in 0.05 second and reduced to 1 g in an additional 0.05 second."

Few engineers understood it and the Armed Forces admitted not being able to reproduce it. Amendment 1 substituted this requirement:

"The equipment shall not suffer damage .....when it is subjected to 30 impact shocks of 30 g, each shock impulse having a time duration of 11, ± 1 millisecond."

This specification is interpreted as meaning that the time for acceleration from 1 g to a maximum of 30 g and return to 1 g shall equal 11 ±1 millisecond.

Discussion of shock testing techniques and equipment brought out many points of view but no prediction as to what the future might hold for aircraft components in this area of performance. It was concluded that a worthy objective was to understand the specifications and attempt to meet them in their current form. If new requirements arose, new equipment could be developed as needed.

The quotation marks around "10 g" were taken directly from the text of the specification. The reason for them, and for the numerous ways of specifying shock test, became more evident as the search for equipment developed. The impossibility of defining a shock independent of time had led to the use of "10 g" as a symbol without meaning. As had happened in other fields of application, the solution of this problem had assumed two phases: first, the definition of "standard" machines to describe the means of administering the shock; second, an investigation into methods of recording and repeating definite acceleration-time curves.

The "standard" machine which appeared to match best the requirements of the program was observed in operation both at Wright Field and at the Naval Research Laboratory. It is known as the "light weight" or "electronic" shock machine and was developed by the Boston Naval District in conjunction with a manufacturer in Rhode Island. Several duplicate units were built and distributed for use as calibrated shock devices.

The anvil plate of this machine weighs 70 pounds. The test load can be approximately equal to that value. A 150-pound hammer can be dropped 36 inches to deliver the maximum blow.

The standard light-weight Navy machine is shown in Figure 6.

It will be used in conjunction with acceleration-sensitive pickups which will record the time-acceleration characteristics of the shock effect on the unit undergoing tests.

Investigation of the control and reproduction of shock waves was taking place at Wright Field. A machine had

Figure 7 (left). Mechanical vibration machine for 0-to-100-cycle range

Figure 8 (above). Electromagnetic vibration exciter

been developed there which delivered the shock by dropping into a sand pit a platform carrying the test piece. Magnitude of accelerations and time of duration could be controlled by height of fall and configuration of blocks placed on the under side of the platform. Stopping times up to 100-milliseconds duration had been recorded on an oscillograph by pickups attached to the device under test.

It was concluded that the Navy machine would satisfy current specification requirements and that a different machine could be obtained if and when specifications reflected new approaches to the defining and generation of shock waves.

Vibration

Most official specifications define vibration tests in terms similar to the following excerpt from AN-M-10a[3]:

"The motor shall be subjected to vibration consisting of simple harmonic motion, having an amplitude of approximately 0.03 inch (maximum total excursion of 0.06 inch), and a frequency varied uniformly between the limits of 10 and 55 cycles per second. The period of variation shall be from one to five minutes."

Other specifications confine the period of variation to one minute. The latest motor specification AN-M-40[1] calls for an increased frequency range of 10 to 100 cycles per second. Inverters, on the other hand, need meet only 0.03-inch total excursion.

United States Air Force Specification 41065B[4] paves the way for examination of vibration characteristics of aircraft components up to a frequency of 500 cycles per second at 20 *g* (0.00152-inch total excursion). This document also describes a method of test which is gathering increased usage. The test piece is vibrated at low amplitude through a given range of frequency. Resonant points are determined by observation and the piece is given extended test at each such point.

Other specifications, written for components designed for specific applications, include long periods of vibration at single frequencies. A propeller pitch motor for instance, must pass a 60-hour test at 240 cycles per second. Other devices are vibrated at 135 cycles per second.

Search for a design goal in the matter of vibration testing brought out the fact that knowledge about vibrations present in aircraft exceeded the ability of available test equipment to reproduce these conditions. For tests at single frequencies and small excursions, tailor-made exciters and resonant beam devices had been used with success. However the problem of exploring a range of frequencies above 100 cycles per second, either in short steps or continuously, had not been solved. Although frequencies as high as 10,000 cycles per second had been recorded in operating aircraft, few applicable specifications actually involved range testing above 100 cycles per second. Increasing specified ranges to 200 cycles were under official consideration. It was decided to purchase available vibration testing equipment and to keep abreast of the art as progress developed.

Investigation of equipment being used to make vibration test on this class of equipment discovered two types of machine, mechanical and electromagnetic.

Mechanical Vibrators

Mechanical vibrators, Figure 7 are equipped with a table approximately 18 inches square on which the work to be tested is mounted. By means of belts and cams, an electric motor drives the table linearly or circularly at a specified excursion and frequency. Cam adjustments control excursion, while motor speed determines frequency. Early machines were developed to match the 0.06-inch 10-55 cycle specification in AN-M-10a[3]. They were equipped with a control which automatically produced the range cycling within the required 1 to 5 minutes. This "brute force" approach to vibration generation was rough on the testing machines and maintenance was fairly high. Even at 55 cycles, the life of the early machines was limited. A new improved design was developed. It was of sufficient size to carry the weights involved, and could be used to 100 cycles per second. An improved lubrication system and modified mounting of auxiliary equipment had rendered it a more acceptable device. It was decided to purchase one of these machines for this phase of the vibration testing program.

Electromagnetic Vibrators

Electromagnetic vibrators of the loudspeaker type were finding extensive use as exciters of resonant beams to obtain tests at fixed frequencies, Figure 8. Power supplies to drive the exciters up to 500 cycles per second were available, and point-to-point explorations of vibration resistance in that range could be made. The control problem involved in automatically testing at constant "g" and variable amplitude over a range of frequencies is a complex one. So, too, is the constant amplitude–variable-"g" test. To date no such automatic control is available, but the exciter can be a useful tool under manual control.

For the purposes of satisfying immediate testing problems, it was concluded that the mechanical machine could be used for exploration and extended tests,

including cycling, up to 100 cycles per second. The electromagnetic exciter could be devoted to explorations of performance at low amplitudes between 100 and 500 cycles per second. If it became necessary to make extended tests at specific frequencies in the range, the exciter could be used in conjunction with a resonant beam. The exciter is rated at 200 pounds thrust. The armature weighs 10 pounds and can deliver maximum excursions of one inch. With a 10-pound load, the 10-pound armature can produce maximum accelerations of 10 *g*. For higher accelerations or appreciably larger loads, the use of resonant beams is mandatory.

This phase of the test equipment program emphasized the urgent need for a heavy duty, adjustable or continuously variable resonant beam system. Used in conjunction with an electronically powered exciter and controlled by feed back from the operating bar, the combination would be useful as a cycling device in the region above 100 cycles per second. Furthermore, tests of long duration could more readily be performed.

At least two approaches to the problem have been initiated. One involves the use of bars and weights in which resonance is controlled by the position of the weights along the bar. The second is based on providing a variable-pressure compressed air cushion which acts as a controllable and continuously variable spring. The principle has been successfully demonstrated on a small model and some plans are under way to adapt it to systems involving test loads of 100 pounds.

Conclusion

Already complex electrical, mechanical, and environmental performance requirements for electric rotating machinery designed for aircraft are continually becoming more involved. Only through the expenditure of many man-hours and much money can a manufacturer equip himself to evaluate completely his designs. Additional work is needed toward providing more exact methods of specifying and testing for the mechanical environments of shock and vibration.

A PAPER by Kuehni and Peterson[1] described the differential analyzer which was placed in service at the General Electric Company shortly after the beginning of World War II. The paper described the basic analyzer and the then new servo amplifiers for use with the integrators. The original amplifiers have been replaced by modified amplifiers of the type developed by the General Electric Company for the analyzer built for the University of California.

Several papers have been written[2,3,4] describing the analyzer and the variety of complex problems which can be studied effectively with this machine.

The range of the analyzer is being continuously extended by the development of special devices which will generate auxiliary functions and assist in the representing of physical detail, thus, in effect, increasing the number of integrators available for the solution of a given problem.

The initial installation of the analyzer included provisions for generating many functions without the aid of integrators. These functions are discussed in the following sections: Curve Input; Vector Summation; Generation of Sinusoids on the Polar Input Table; Multiplication of Two Variables; and Phase Angle Determination. These functions in general required operators to track a curve or follow a template by turning a crank which was geared to an indicator. The development of an automatic follower has led to the possibility of performing all of these functions automatically. The automatic follower and applications of this follower will now be described.

Paper 50-215, recommended by the AIEE Computing Devices Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted March 14, 1950; made available for printing August 8, 1950.

A. C. Cook and L. K. Kirchmayer are with the General Electric Company, Schenectady, N. Y., and C. N. Weygandt is with the University of Pennsylvania, Philadelphia, Pa.

The Automatic Follower

A sectional sketch of the follower is shown in Figure 1. It will be noted that there is a light source A and two paths for the light. One path is through the window W to phototube B. This is a reference amount of light which can be adjusted. The other path is through the lens L to the viewing aperture O and by reflection to phototube C. It is possible to adjust the window W so that the light on phototube B is equal to the reflected light at C when the viewing aperture of the follower scans a surface which is half black and half white, Figure 2. The follower can be adjusted to follow the edge of a template.

The phototubes form part of a bridge circuit which serves as the input to a preamplifier. The preamplifier provides a signal to the main amplifier, which controls an amplidyne-motor drive geared to the follower head. The servo loop is shown in Figure 3.

Automatic Operation

The application of the automatic follower to the functions mentioned previously is now discussed.

The Automatic Curve Follower

Functions of the form of equation 1 can be generated by means of the input tables of the analyzer

$$y=f(x) \tag{1}$$

In earlier applications, an operator tracked a plotted input curve by hand, turning a crank which fed $f(x)$ to the problem. Application of the automatic follower to the task of curve following has eliminated the necessity for additional man power for manual operation and also has reduced the error considerably.

The curves to be followed are ordinarily prepared with black ink against a white background. As Figure 2 shows, the curve must be colored solidly for a depth of about one inch along one side. Templates also can be prepared for various functions. The follower has been used to follow templates (usually moving templates) in applications to be discussed later.

Figure 4 shows the automatic follower arranged for following a function such as equation 1.

The Vector Mechanism

There are many problems where the vector sum of the x and y components is needed. The summation of these rectangular components is accomplished by means of the vector mechanism shown schematically in Figure 5. S is the input shaft which drives the lead screw and positions the target which is a bakelite template (although it is not shown by Figure 5, S must actually be supplied through corrective gearing to compensate for the error caused by rotation of vector arm). There is a protruding surface on the follower head which slides freely in the channel-like body of the vector mechanism and provides the angular relationship for the vector arm. If the motion x and y is supplied by the analyzer, the automatic follower can supply the motion S so that the target is always

Figure 1. Sectional view of follower head

Figure 2 (left). Portion of curve viewed by follower head

Figure 3 (right). Servo loop for the automatic follower

Figure 5. Vector arm mechanism

beneath the indicator and equation 2 is the relationship which results

$$S=\sqrt{x^2+y^2} \qquad (2)$$

The vector mechanism with the automatic follower is shown in Figure 6.

Provision has been made also to supply the phase angle of the vector sum. In Figure 6 there is a large protractor beneath the vector mechanism and a pointer attached to the heel of the vector arm. An operator can read the angle of the vector sum and manually supply the variable θ to the problem by causing the counter in Figure 7 to agree with the angle read from the protractor. This operation is not automatic, but it can be made so (see the section on Phase Angle) if one is willing to supply the vector magnitude manually.

The Generation of Sinusoids by Polar Input Table

The sine or cosine function can be generated by two integrators solving the equation

$$\frac{d^2x}{dt^2}=-x \qquad (3)$$

but frequently a means of obtaining the sine or cosine, without the need for integrators, is sought. If a dot or mark is placed near the outer end of a radius of the polar table and the polar table given a motion θ, the sine θ may be generated by an operator turning the vertical lead screw so that an indicator is always aligned with the dot. Simultaneously the motion $\cos\theta$ must be applied to the horizontal lead screw by the same, or by another, operator.

The automatic follower has made it possible to generate either the sine or cosine function automatically.

The device functions as follows: A small circular template (1-inch diameter) is placed on the polar table as in Figure 8. The follower is mounted on the vertical lead screw and the servo motor drives the follower so that it always aligns with the bottom edge of the small circular template.

It is necessary that an external means provide $\cos\theta$ to the horizontal lead screw. If two polar tables are available, $\sin\theta$ can be generated on one and $\cos\theta$ on the other, so that the whole operation is automatic.

A further valuable application of this device is obtained when $\sin\theta$ and $\cos\theta$ are given, and the angle θ is desired. The angle θ can be obtained automatically from this device by attaching the servo

Figure 8 (lower left). Polar table with 1-inch circular template

Figure 10 (right). Polar table with straight line template

motor to the polar table, or θ drive. The magnitude of θ is not limited.

The Automatic Multiplication of Two Variables

It is a well-known fact that the product of two variables can be obtained from a 2-integrator setup solving equation 4

$$uv = \int u\,dv + \int v\,du \tag{4}$$

A device which will multiply directly without the use of integrators has been in use for many years.

This device is obtained by modifying the polar table mechanism so that a diametral line across the polar table is moved through an angle θ by a tangent bar so as to satisfy equation 5.

$$\tan\theta = z/k \tag{5}$$

where z is the input variable to the tangent bar lead screw and k is a constant associated with the geometry of the system.

Early applications required an operator to keep the index on the vertical lead screw aligned with the straight line (diameter of polar table) and by so doing produced a relationship of equation 6

$$\tan\theta = y/x \tag{6}$$

where y was the motion of the horizontal lead screw and x the hand-cranked motion of the vertical lead screw.

Combining equations 5 and 6, it can be seen that

$$y = zx/k \tag{7}$$

This operation has been made automatic by replacing the straight line with a template and using the automatic follower. The servo motor then positions the vertical lead screw to satisfy equation 7. The automatic multiplier is shown in Figure 9.

It will be observed that this scheme can be used to obtain the quotient of two variables by solving equation 7 for x, using the servo motor to drive the horizontal lead screw

$$x = ky/z \tag{8}$$

However, the denominator must not be allowed to approach zero.

Figure 9. Polar table arranged for automatic multiplying operation

Phase Angle

A new application arises by using the straight line template of the section preceding to determine the phase angle between the vector sum and one of its components. This phase angle is obtained automatically by supplying the two components x and y in Figure 10 as horizontal and vertical drives respectively and gearing the servo motor to the polar table to drive θ. The follower head mounted on the vertical lead screw provides the signal to the motor.

The vector magnitude can be obtained simultaneously from this application by having an operator interpolate the vector magnitude from the graduations provided on the template. This is the inverse of the operation in the section on The Vector Mechanism where the vector magnitude was obtained automatically and the angle was obtained by means of an operator reading a scale.

Other Devices

Numerous other devices have been developed for use on the analyzer either to make the operation more nearly auto-

Figure 11(A). Actual amplifier characteristic. (B). Approximate amplifier characteristic

Figure 14 (above). Schematic arrangement of components for representing change of gear ratio

Figure 15. Schematic arrangement of components for representing the combined effect of saturation and change in gear ratio

matic or to enable a more accurate representation of physical systems. Some of these devices are: Gear Ratio Selector; Remote Indicator; Transportation Lag Device; Recording Counter; Deadband Units; and Disconnect Units.

Gear Ratio Selector

The representation of control systems on the differential analyzer brings about the need to represent amplifiers whose gain for positive signal is different from the gain for negative signal. Also, the need for representing saturation arises with these problems. Figure 11(A) shows an amplifier characteristic in which both conditions exist.

The actual curve of Figure 11(A) could be represented on an input table and the function could be fed into the analyzer automatically by using an automatic follower. Frequently, though, input tables are needed for other functions, and when an input table is not available an automatic shaft-locking device can be used to produce a function such as Figure 11(B) which is an approximation to Figure 11(A). Differential gears must be used in conjunction with the automatic shaft-locking device.

This automatic shaft-locking device is shown schematically in Figure 12. A braking bar (with gear teeth to insure positive grip) is pivoted on a lower shaft of the pillow block. When solenoid *a* is energized, the braking bar locks shaft *a*; when solenoid *b* is energized, the braking bar locks shaft *b*.

To represent saturation only, the shaft-locking device is used as in Figure 13.

When the output is proportional to the input, shaft *a* must be locked; when the output is saturated, shaft *b* must be locked.

To represent the change in gear ratio corresponding to the change in amplification factor, two differential gears are required with the shaft-locking device. Figure 14 shows that when the output is to be driven by input *1*, shaft *a* must be locked and when the output is to be driven by input *2*, shaft *b* must be locked.

These operations can be made automatic by including a lead screw-operated microswitch which energizes either solenoid *a* or solenoid *b*.

To represent the function of Figure 11(B) both saturation and gear-ratio change must be represented. This requires a connection such as Figure 15.

Remote Indicators

Many problems require inputs which are functions of more than one variable. Such inputs can be generated as long as the progress of all variables can be observed readily by an operator. The functions are prepared as in Figure 16 for use on the input tables in the form of a family of curves. The analyzer provides the vertical drive y and the progress of z is given by the counter. In the past the counter was driven by a flexible shaft, but some difficulty arose because of the backlash in the flexible shaft drive. Hence a system of selsyn motors driven by selsyn generators has been adopted.

Since the progress of z is known, an operator can position the horizontal lead-screw so that the indicator aligns with the proper magnitude of z and y. This solves equation 9 for x

$$x = f(y, z) \tag{9}$$

The process is one of the interpolation which is not difficult, since ordinarily the variables involved are not moving rapidly. As a matter of fact, functions of three variables have been generated by this means, so that an equation of the form of equation 10 was solved

$$x = f(y, z, w) \tag{10}$$

Figure 16 (left). Rectangular input table with function of two variables

Figure 17 (right). Selsyn motor and counter

Figure 18. Rectangular input table arranged to generate $F(t) = f(t\text{-}a)$

Figure 19. Rectangular input table arranged for generating $F(t) = f(t) - f(t\text{-}a)$

The selsyn generators are capable of driving more than one motor. A typical selsyn-driven counter is shown in Figure 17.

Transportation Lag Device

Problems have been encountered where the magnitude of a function $f(t)$ as it was at some previous time $(t-a)$ was desired as an input. This requires a form of memory.

The function is generated on the analyzer by plotting the function $f(t)$ and arranging a scale on the vertical carriage as shown in Figure 18. An operator is required to read the magnitude of the function a units behind the plotting pen. The operator cranks the counter to agree with the scale reading and produces the function

$$F(t) = f(t-a) \tag{11}$$

The distance a is adjustable.

In certain color register control problems it has been necessary to generate the function $F(t) = f(t) - f(t-a)$. For this application the scale is attached to the plotting pen, as shown in Figure 19. An operator provides $F(t) = f(t) - f(t-a)$ directly by cranking the counter to agree with the scale. Here also the distance a is adjustable.

Recording Counter

Four quantities can be plotted on the output tables, and for cases where the input tables are not in use, four more output plots may be obtained. However, the input tables are seldom idle and the need for more output information than the four curve plots had led to the use of a recording counter (this recording counter is a modified version of the one developed by Massachusetts Institute of Technology for their original analyzer). The recording counter is shown in Figure 20.

There are two features of the recording counter which are sometimes of advantage: one, the numerical results from the counter preserve a higher degree of accuracy than a plot; and two, facilitate any arithmetic manipulations of the results which may be required. For example, a derivative can be obtained by preparing a table of first differences from the recorded numerical data. This first difference method has been of value in machine studies where only the integral of the torque was conveniently available and the torque itself was desired. Ordinarily, however, it is more convenient to have results in curve form.

Deadband Units

Kuehni and Peterson[1] have described the deadband units. These units are used to represent discontinuities, such as backlash in control systems.

Disconnect Units

In control problems the need for representing overriding signals is simplified by using a unit called a disconnect unit. A sectional view and an end view of the disconnect unit are shown in Figure 21. The disconnect unit is used in place of a normal coupling and when the drive is to be open-circuited the ring is moved to the right so that the pin disengages from the hole in Figure 21. To re-engage the drive, the ring must be moved to the left so that the pin enters one of the holes.

To accommodate a complex system of input signals, all possible signals are provided with a complete path to the input point and one disconnect is included in the drive of each signal. As the driving signals must be changed, combinations are quickly selected by means of the disconnect units. It is a simple matter to open the disconnect unit of unwanted drives and to close the unit of the desired drives. The chief gain is in the speed of connecting and disconnecting the driving shafts.

The automatic shaft-locking device described previously provides a means of manipulating overriding signals automatically.

Inverse Integration

The normal integrator equation is obtained from Figure 22

Figure 20. Automatic recording counter

Figure 21 (below). Disconnect unit

Figure 22 (right). Schematic integrator

$$UdV = BdW \tag{12}$$

where U represents the integrand variable, V represents the differential, W represents the integral or output, and B is a constant associated with the mechanical system. Equation 12 can be solved in three ways:

1. Given U and V solve for W

$$W = \frac{1}{B}\int UdV \tag{13}$$

2. Given W and U solve for V

$$V = B\int \frac{dW}{U} \tag{14}$$

3. Given W and V solve for U

$$U = B\frac{dW}{dV} \tag{15}$$

It will be observed that for each method the solved-for variable must be driven by the servo motor.

The first method is quickly recognized as the common form of the integrator equation where straightforward integration is being performed and the integral W is driven by the servo motor.

The second method will be recognized as inverse integration where the servo motor must be connected to the V shaft. Bush and Caldwell[5] have described this connection. Ordinarily the servo motor is permanently geared to the W shaft. However, two of the integrators on the General Electric Analyzer have been provided with external servo motors which can be geared to any shaft. This makes inverse integration easily possible and has been found to be a valuable feature.

The third method suggests a means of obtaining a derivative by arranging to have the servo motor drive the U shaft. However, certain practical problems have so far prevented the use of this connection.

Discussion

D. Lebell (University of California, Los Angeles, Calif.): This paper is of particular interest to those of us who have been operating the University of California differential analyzer. As would be expected, several of the limitations and special problems which the authors have encountered in operating the General Electric differential analyzer have occurred in our work also. It may be of interest to point out differences in our respective solutions to these difficulties.

The Automatic Follower

The University of California automatic curve follower differs from General Electric's in that it is designed to follow an inked line rather than the boundary between a dark and light region. This is achieved by utilizing the reflection of two light beams which straddle the line to be followed. Two photocells arranged in a bridge circuit convert any difference in the intensity of the reflected light beams to an electrical error signal. This error signal after suitable amplification is made to control the servo motor in much the same manner as is described in the paper. It is interesting to note that the automatic follower employed in the differential analyzer described by Walther and Dreyer,[1] is similar to General Electric's in that it employs a 1-hole aperture. The aperture diameter appears to be sufficiently small to permit following of one edge of the line describing the function.

Figure 1. Alternate method for performing inverse integration

Inverse Integration

An alternate method for performing inverse integration which requires no special modification of equipment is shown in Figure 1 of this discussion. It has proved quite satisfactory except, of course, in the neighborhood where $1/u \rightarrow \pm\infty$.

A. C. Cook: The authors wish to express their appreciation for Mr. Lebell's discussion and for the benefit of the readers wish to say that the analyzers at the University of California, the University of Pennsylvania, and at the General Electric Company are similar analyzers. With these analyzers the integrators, the interconnection system, and the functional inputs are all mechanical, while the integrator follow-up systems and the automatic followers have electronic amplifiers to control their servo motors.

We were pleased to learn that a line follower had been built for the California analyzer. We recognize definite advantages to the automatic line follower. The General Electric Company has available such a follower which at present is being applied to industrial applications for contour following on automatic machine tools.[1]

Mr. Lebell indicates an alternative method for performing inverse integration. This method is similar to the regenerative connection proposed by Amble.[2] There are a number of functions which can be accomplished by the regenerative technique and Michel[3] gives a method for synthesizing these connections. Several of the regenerative schemes work very well, but most of them require extra precautions to avoid unstable conditions.

Economical Design of a 3-Phase Transformer

LADISLAV CIGANEK
MEMBER AIEE

A TRANSFORMER of a given output P, frequency f, and voltage ratio U_1/U_2 can be designed to perform its duties at a lowest possible production price. Choice of main dimensions, however, is very limited by the complicated mutual relations which result from economic and performance requirements.

The following considerations prove that exact values of core loss P_{Fe}, copper loss P_{Cu}, impedance voltage e_z, and no-load current I_0, as prescribed by the national standards of different countries, limit the design so much that only one set of dimensions conforms to all requirements. Sometimes even an exact solution is impossible. The most economical design can be derived from the exact solution by varying prescribed performance data within allowances. Considerations are restricted to the 3-phase core-type transformer with concentric windings and natural oil cooling. Similar method applies to other types of transformers.

It is advantageous that, unlike rotating machinery, both core and windings of the transformer can be so widely subdivided to provide for necessary cooling ducts and surfaces, that preliminary design can be performed regardless of the cooling requirements.

Core loss of the transformer

$$P_{Fe}=Q_{Fe}w_B \tag{1}$$

Q_{Fe} = core weight, w_B = per-unit weight loss of the assembled core at a maximum flux density B and frequency f. In Figure 1, w_B plotted against B corresponds to page 150 of reference 1 for 29-gauge 4.2 per cent silicon steel at 60 cycles with 10 per cent increase due to stamping burrs.

The no-load current is practically only magnetising current. Assuming equal density in legs and yokes, the per cent no load current

$$I_0=\frac{100Q_{Fe}v_B}{3U_1I_1} \tag{2}$$

v_B is the reactive power input needed to magnetise a unit weight of laminations to the maximum density B at a frequency f. In Figure 1, v_B plotted against B is for the same material as the plot of w_B (page 192 of reference 1).

Using equations 1 and 2 the following ratio is obtained

$$\frac{v_B}{w_B}=\frac{PI_0}{P_{Fe}100} \tag{3}$$

The ratio v_B/w_B plotted against B in Figure 1 determines only the flux density conforming to both core-loss and no-load requirements.

Main dimensions of the transformer core and windings are represented by Figure 2. Insulation clearances b, c, and d, according to present practice (references 2, 3, 4), are plotted against higher voltage. Thickness of both coils a_1+a_2 as well as low-voltage coil-core clearance e are plotted against diameter D of the leg-section circumscribing circle. Coil thicknesses vary very little with a transformer of a given output[2] in concord with Schwartz,[5] who proved that the window width is constant for a given output and voltage. Value e varies more with the lower voltage and cooling conditions; variations, however, affect the results very little.

For further considerations the main dimensions are expressed in relation to the leg diameter D.

Length of the high-voltage coil

$$L_c=\lambda D \tag{4}$$

The distance between the center line of neighboring coils

$$M=\mu D=D+2(e+b+a_1+a_2)+c \tag{5}$$

Mean diameter of windings for reactance calculation

$$D_m=\delta D=D+2e+b+a_1+a_2 \tag{6}$$

Net section of core leg

$$S_c=\alpha D^2 \tag{7}$$

For three steps of the core section (Figure 2) and 0.9 stacking factor α equals 0.61. It grows up to 0.65 with a 5-step core section. Cooling passages and clamping devices reduce α a little.

Equivalent length of the core with constant section S_c according to Figure 2

$$l_{Fe}=\zeta D=3L_c+4M+6d+1.5D=\left(3\lambda+4\mu+6\frac{d}{D}+1.5\right)D \tag{8}$$

The core weight

$$Q_{Fe}=\alpha\zeta\gamma_{Fe}D^3 \tag{9}$$

γ_{Fe} = per-unit weight of laminations (7.6×10^{-3} kilograms/cubic centimeter). ζ varies between 14 and 20 with an average of 17. Assuming $\alpha=0.61$ and taking Q_{Fe} from equation 1, the preliminary diameter

$$D_p=2.34\sqrt[3]{Q_{Fe}} \tag{10}$$

With help of this value and of dimensions given by Figure 2, μ and δ are computed from equations 5 and 6. They are practically constant for a given transformer output and voltage.[3]

Relative coil length λ is determined chiefly by the necessary reactance. The per cent reactance

$$e_x=\sqrt{e_z^2-e_r^2} \tag{11}$$

where the per cent resistance

$$e_r=100\frac{P_{Cu}}{P} \tag{12}$$

Paper 50-216, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Oklahoma, October 23–27, 1950; manuscript submitted November 21, 1949; made available for printing August 10, 1950.

LADISLAV CIGANEK is Professor of Electric Machinery, Technical University, Bratislava, Czechoslovakia.

With dimensions in centimeter, neglecting minor factors, the per cent reactance

$$e_x = \frac{4.25\times10^8 P b_e \delta}{\alpha^2 f \lambda B^2 D^4} \tag{13}$$

where equivalent clearance between coils

$$b_e = b + \frac{a_1 + a_2}{3} \tag{14}$$

D corresponding simultaneously to equations 9 and 13 offers simple relation

$$\lambda = (3\lambda + K)^{4/3} A \tag{15}$$

with constants

$$K = 4\mu + 6d/D + 1.5 \tag{16}$$

and

$$A = \frac{6.3\times10^6 P b_e \delta}{\alpha^{3/2} Q_{Fe}{}^{1/2} f e_x B^2} \tag{17}$$

Solution of equation 15 gives the only possible set of dimensions of the transformer core. The function $\lambda = f(A)$ for constant K is represented by Figure 3. Two values of λ conform to every A up to A_{max}. The higher value is economically unsound, because it results in very high transformer price. Solution

$$\frac{dA}{d\lambda} = 0$$

determines that

$$A_{max} = 0.156\lambda^{-1/3} \tag{18}$$

for $\lambda = K$.

Equation 15 is solved graphically by the chart system of Figure 4 with $K = 7 - 12 = 12$ as parameters. Should the computed A fall above A_{max} no set of dimensions conforms to all requirements. Reduction of A can be achieved, according to equation 17 solely by increase of P_{Fe}, giving higher Q_{Fe}, or higher B, or both.

Design procedure according to offered method is represented by the example of a 200-kva transformer, operating at 22 kv, 60 cycles. American practice gives (page 916 of reference 6.)

$P_{Fe} = 985$ watts

$P_{Cu} = 2830$ watts

$e_x = 5.2$ per cent

I_0 is not prescribed, Czechoslovak standards require for this type that I_0 equal 6.2 per cent with ±30-per cent allowance.

$$\frac{v_B}{w_B} = \frac{200\times10^3\times6.2}{985\times10^3} = 12.6 \text{ volt-amperes per watt} \tag{3}$$

From Figure 1

$B = 14350$ gauss

$w_B = 2.84$ watts per kilogram

$$Q_{Fe} = \frac{985}{2.84} = 348 \text{ kilograms} \tag{1}$$

$$D_p = 2.34\sqrt[3]{348} = 16.5 \text{ centimeters} \tag{10}$$

From Figure 2

$b = 1.5$ centimeters

$c = 2$ centimeters

$d = 2.8$ centimeters

$e = 0.6$ centimeter

$a_1 + a_2 = 4.3$ centimeters

$$M = 16.5 + 2(0.6 + 1.5 + 4.3) + 2 = 31.3 \text{ centimeters} \tag{5}$$

Therefore

$$\mu = \frac{31.3}{16.5} = 1.9$$

$$D_m = 16.5 + 2\times0.6 + 1.5 + 4.3 = 23.5 \text{ centimeters}$$

Therefore

$$\delta = \frac{23.5}{16.5} = 1.43 \tag{12}$$

$$e_r = \frac{100\times2830}{200\times10^3} = 1.415 \text{ per cent}$$

$$e_x = \sqrt{5.2^2 - 1.415^2} = 5 \text{ per cent} \tag{11}$$

$$b_e = 1.5 + \frac{4.3}{3} = 2.93 \text{ centimeters} \tag{14}$$

$$K = 4\times1.9 + 6\times\frac{2.8}{16.5} + 1.5 = 10.1 \tag{16}$$

$$A = \frac{6.3\times10^6\times200\times10^3\times2.93\times1.43}{(0.61)^{3/2}(348)^{4/3}\times60\times5(14350)^2} = 0.0497 \tag{17}$$

From Figure 4

$\lambda = 2$

$$\zeta = 3\times2 + 10.1 = 16.1 \tag{8}$$

$$D = \sqrt{\frac{348\times10^3}{7.6\times0.61\times16.1}} = 16.8 \text{ centimeters} \tag{9}$$

$$L_c = 2\times16.8 = 33.6 \text{ centimeters} \tag{4}$$

From Figure 2

$L = 33.6 + 2\times2.8 = 39.2$ centimeters

Figure 1 (left). Per-unit loss and magnetising input of the 29-gauge 4.2 per cent silicon steel at 60 cycles

Figure 2 (right). Main dimensions of the 3-phase core transformer

Figure 3. Function $\lambda = f(A)$ for $K=10$

Figure 4. Solution of equation 15

$$M = 16.8 + 2(0.6 + 1.5 + 4.3) + 2 = 31.6 \text{ centimeters} \quad (5)$$

It is interesting to note that very wide variations of I_0 affect A and therefore the dimensions of the core vary little. In fact, a variation of B between 13 and 16 kilogausses gives practically no change in core dimensions. An increase of B is compensated by the reduction of Q_{Fe} and vice versa.

A slight deviation from the performance standards may result in more economical design. I_0 having widest allowances of all values, it is advisable to keep other values unchanged and proceed to the optimum solution as follows.

Using equations 15, 8, 17, and 1 to obtain values of λ_0, ξ_0, A_0 and Q_{Fe0} respectively. New value of λ gives new

$$A = \frac{\lambda}{(3\lambda + K)^{1/2}}$$

Corresponding core weight

$$Q_{Fe} = Q_{Fe0}\left(\frac{A_0}{A}\right)^{3/4} \quad (19)$$

With B and w_p unchanged, the loss in legs and yokes respectively are

$$P_l = Q_{Fe} w_p \frac{3\lambda + 6d/D}{3\lambda + K} \quad (20)$$

$$P_y = Q_{Fe} w_p \frac{4\mu + 1.5}{3\lambda + K} \quad (21)$$

With $\lambda < \lambda_0$, the resulting core loss is higher than the prescribed P_{Fe}. Increase can be compensated for by increasing the yoke section and thereby reducing flux density. In narrow limits of B, unit loss increases with B^2. Therefore, an increase of yoke section results in a linear decrease of yoke loss. The new yoke weight necessary to keep prescribed core loss with leg loss unchanged is then

$$Q_y = Q_{Fe} \frac{4\mu + 1.5}{3\lambda + K} \frac{P_y}{P_{Fe} - P_l} \quad (22)$$

The new core weight

$$Q_{Fe2} = \frac{Q_{Fe}}{3\lambda + K}\left[3\lambda + 6d/D + \frac{P_y}{P_{Fe} - P_l}(4\mu + 1.5)\right] \quad (23)$$

The corresponding no-load current will be lower than prescribed. With $\lambda > \lambda_0$, the yoke section should be reduced to keep core loss the same, and I_0 is higher than required.

Assuming equal ampere loading of both low- and high-voltage windings, the weight of all windings

$$Q_{Cu} = 6\pi\delta D N_1 s_1 \gamma_{Cu}$$

where N_1 is the primary turns per phase and s_1 is the section of primary conductor. Taking $\gamma_{Cu} = 8.9 \times 10^{-3}$ kilogram per cubic centimeter and the specific resistance $\rho = 2.2 \times 10^{-4}$ ohm centimeter for copper at 70 degrees centigrade

$$Q_{Cu} = \frac{4 \times 10^3}{P_{Cu}}\left(\frac{P\delta}{B\alpha Df}\right)^2 \quad (24)$$

With the low-voltage winding in zigzag, the weight increases by 7.5 per cent. Allowance for stray losses is to be taken for heavy conductors.

Changing λ_0 in λ, the original copper weight Q_{Cu0} changes in

Figure 5. Price function of the 200-kva transformer

$$Q_{Cu} = Q_{Cu0}\left(\frac{\lambda}{\lambda_0}\right)^{1/2} \tag{25}$$

according to equations 9 and 24.

The price of the complete transformer

$$C = p_{Fe}Q_{Fe} + p_{Cu}Q_{Cu} + C_k$$

where p_{Fe} and p_{Cu} are the per-unit prices of the assembled core and windings respectively. C_k is the constant part of the price, including tank, oil, bushings, and so forth.

Substituting from equations 18 through 25, the price formula has a form

$$C = p_{Fe}Q_{Fe0}\frac{\lambda_0^{3/4}}{\xi_0}\left[3\lambda^{1/4} + 6\frac{d}{D}\lambda^{-3/4} + \frac{(4\mu+1.5)^2}{\frac{\xi_0}{\lambda_0^{3/4}}\lambda^{3/4} - 3\lambda^{1/4} - 6\frac{d}{D}\lambda^{3/4}}\right] + p_{Cu0}Q_{Cu0}\left(\frac{\lambda}{\lambda_0}\right)^{1/2} + C_k \tag{26}$$

A minimum price results from

$$\frac{dC}{d\lambda} = 0$$

where λ conforms to the following equation

$$X\lambda^{1/4} + \frac{\lambda - N}{\lambda} = Y\frac{2M\lambda^{-1/4} - 7 - N\lambda^{-1}}{(M\lambda^{3/4} - 3\lambda - N)^2} \tag{27}$$

with constants

$$X = \frac{2p_{Cu}Q_{Cu0}\xi_0}{3p_{Fe}Q_{Fe0}\lambda_0^{3/4}}$$

$$Y = (4\mu + 1.5)^2$$

$$M = \frac{\xi_0}{\lambda_0^{3/4}}$$

$$N = 6d/D$$

The function expressed by equation 26 has a very flat minimum. It is, therefore, very convenient to trace $C = f(\lambda)$ by computing values of variable part of C for $\lambda = 1, 2, 3, 4$, and 5. A curve, such as in Figure 5 offers to a designer full range of values of λ, giving a price close to the minimum. The design can then be refined with respect to the laminations and conductor dimensions, as well as to other items which up to now were not taken into consideration. Variable part of the price

$$C_v = Q_{Fe2} + \frac{p_{Cu}}{p_{Fe}}Q_{Cu} \tag{28}$$

is computed with help of equations 19 through 24. For the transformer of the preceding example values are given in Table I.

Table I

λ	A	Q_{Fe}	P_l	P_y	$P_{Fe}-P_l$	Q_{Fe2}	Q_{Cu}	C_v
1	0.0322	484	420	955	565	718	107	1,039
2	0.0497					348	151	901
2.15	0.0524	337	430	527	555	327	156	795
3	0.0576	301	450	410	535	268	185	823
4	0.0646	237	480	338	505	249	213	888
5	0.0685	273	494	282	491	231	239	948

The optimum design corresponds to $\lambda = 2.15$ obtained from equation 27. Results are represented by Figure 5. The ratio p_{Cu}/p_{Fe} was assumed to be 3. Additional curves for p_{Cu}/p_{Fe} equal to 2 and 4 show that the minimum slides towards higher λ with the reduction of p_{Cu}/p_{Fe}. The price function has such a flat minimum that +5 per cent allowance in the variable part of the price gives λ in the limits 1.5 to 3.2. In Figure 5 both core and windings weight is plotted against λ for comparison.

Very often, no-load current is not prescribed. With only P_{Fe}, P_{Cu} and ε_z given, a new set of equations together with the minimum price condition determine a new λ for each grade of laminations, represented by the equivalent function.

$$w_B = f(B)$$

Solution of the function, however, has very little value, because resulting transformer has a very high flux density B. No-load current is then too high and cooling conditions very poor. It is, therefore, necessary to prescribe at least limits of I_0 to achieve to an economically sound design.

Summary

A method of preliminary design of a 3-phase core transformer is offered, giving lowest priced transformer conforming to performance requirements of core loss, copper loss, per cent impedance and no-load current. A flat minimum of the resulting price function allows further refinements of the design. The only empirical values used in the procedure are the insulation clearances and coil thicknesses given by Figure 2. Technological improvements are introduced in the design by corresponding corrections of the charts of Figure 2.

Discussion

G. M. Stein (Westinghouse Electric Corporation, Sharon, Pa.): The author's method of finding the most economical design of a 3-phase transformer is open to question.

The author points out that a transformer of round core section and of a given output, frequency, voltage, short-circuit impedance, copper loss, core loss, and magnetizing current may have only one set of dimensions, unless the yoke widening is varied. This is true and has already been mentioned in a paper of Schwartz[1] referred to by the author.

A transformer which complies with the given performance values exactly is not necessarily the lowest cost design. If, for instance, the condition of a given magnetizing current is omitted, one set of dimensions, like opening height and leg diameter, may be varied, as shown by Schwartz,[1] and the cost will vary accordingly. The minimum cost design thus obtained does not necessarily have the given magnetizing current, but may show a value which is either lower or higher than the required limit. On the other hand, the given magnetizing current may appear in a design which does not have the lowest cost.

If the magnetizing current in the minimum cost design is lower than required, this design is a more economical choice than the one with the given magnetizing current. If, however, the magnetizing current turns out to be too large at the minimum cost, the design with the given current, but of higher cost has to be considered. Again it can be shown that this design may not have the lowest cost. For this purpose the condition of a given core loss is replaced by that of a fixed magnetizing current or of a fixed flux density which practically furnishes the same result. If the core loss in the corresponding minimum cost design is lower than the required limit, this design, and not the one with the given loss, will represent the most economical choice.

As shown by Schwartz, the thickness of the windings and the opening width can

have only one set of values in a transformer of given output, voltage, frequency, copper loss, and short-circuit impedance, regardless of the required core loss and magnetizing current. As a matter of fact, an inspection of equation 9a in the paper by Schwartz shows that a given ratio of resistance to reactance fixes the opening width regardless even of the output.

The author ignores this limiting condition and introduces instead the winding thickness as a function of the leg diameter in Figure 2 of the paper, without mentioning where these values come from. Then he computes his opening height so that the design complies with a given impedance. There is no reason for it, and the author does not show why this design should accommodate the copper weight corresponding to the given copper loss according to his equation 24.

In order to co-ordinate this copper weight with the design, the author would have to introduce winding space factors and current densities, as done by Schwartz, but ignored in the paper discussed.

The author uses a linear relationship between an increase in yoke section and a corresponding decrease in core loss in order to compute the cost as a function of the yoke height. The same assumption was made by Schwartz, but is not true, since the loss in the corners of the core increases with the yoke height. As a result, and as shown by the writer in two papers published in 1933[3] (Figures 3, 4, 5) and 1947[2] (Figures 7, 13, 14), the total core loss decreases towards a constant value if the yoke section is made larger than that of the leg.

Ladislav Ciganek: The purpose of the paper was to show the shortest possible procedure leading to a minimum-priced transformer with P_{Fe}, P_{Cu}, ϵ_z, and I_0 prescribed within fixed limits. Omitting prescription of the magnetizing current, the minimum price condition leads to the design with the flux density high above 20 kilogaus.

This design is useless. It is better to prescribe I_0, than to check afterward to see if the resulting value complies with the requirements.

Values of coil thicknesses in Figure 2 of the paper were taken from practice. It is possible to relate them to the leg diameter D, because this value varies very little with transformers of a given output. This conforms with Schwartz, as the insulation clearances and filling factors vary very little for a fixed output. Schwartz's equation 9a does not prove that the opening width is independent of the output, because resistance–reactance ratio is a characteristic value for only one output. All values in Figure 2 used in further considerations are only in form of relative numbers δ and μ, the results are not affected by possible differences.

Equation 24 of the paper gives the exact value of the copper weight, if copper loss is prescribed. Flux is given by the computed values of B and D and δ is constant for a given output and voltage.

The author is familiar with the fact that core losses in corners and knots are higher than in the linear part of the yoke. The ratio of the yoke section to the core section, however, is never far from 1, and in this case the error is not great. The price function given in Figure 5 of the paper is affected but little thereby.

It was the aim of the author to present a clear concept of mutual relations of different parameters of the transformer, primarily for educational purposes. The majority of the relations is very well known to the transformer designers but some, such as given by Figures 1, 3, 5, are new and author hopes that they will improve design methods.

Control Circuit Transformers

JEROME M. FRANK
MEMBER AIEE

A. J. HAUCK
ASSOCIATE AIEE

CONTROL circuit transformers perform a vital function in many electrical applications. In order to use a control circuit transformer to best advantage, this paper will discuss the electrical design features involved and present a method for obtaining accurate regulation data.

Control circuit transformers are divided into two classes, namely high reactance and low reactance.

High-reactance control transformers are transformers of limited power input, capable of withstanding the short circuiting of the secondary terminals without burnout or excessive heating, and are capable of delivering a greater power output than a doorbell transformer. Examples of this type are chime and furnace damper control transformers.

Low-reactance control transformers are dry-type transformers, designed to limit the terminal voltage drop on overloads to a minimum and to isolate the low-voltage control circuit from the high-voltage power circuit. This paper will limit itself to the low-reactance type and will cover the factors involved in designing and testing control transformers 1/4 kva and larger.

A transformer with a dual voltage primary of 230/460 volts, rated for 60/50 cycles and with a secondary voltage compensated to give 115 volts at rated load at 100 per cent power factor would meet 90 per cent of the applications involved. This transformer would be of the open-type construction for panel mounting and would have either screw-type terminals mounted on the coil or a terminal board.

The two most important factors in the design of a control transformer are the temperature rise and the regulation.

The copper loss, the iron loss, the proportionality between the copper loss and the iron loss, the surface area of the coil and core, and the type of enclosure are the dominent factors in predetermining the temperature rise. The number of watts that can be dissipated from a given surface varies with the frame size and is an experimentally determined constant. The transformers are designed for a 55 degree rise by resistance in accordance with National Electrical Manufacturers Association standards. This rise plus a 40-degree ambient and a 10-degree allowance for hot spots equals 105 degrees, the permissible ultimate temperature for class *A* Insulation. In mounting this transformer in an enclosure, enough surface area and space must be allowed to dissipate the losses of the transformer.

The resistance and reactance of a transformer are usually expressed as a per cent of the rated voltage drop, in order that the regulation of transformers of different voltages and kilovolt-ampere ratings can be directly compared. The per cent of voltage drop through the resistance, *IR*, for example, is found by multiplying the total effective resistance referred to the secondary by the secondary rated current times 100 and then dividing by the rated secondary voltage.

The per cent *IR* is dependent upon the wire size, the number of turns, the length of mean turn, and the temperature rise. For a given temperature rise there is very little that can be done in changing the per cent *IR*, provided the core is proportioned so that the mean length of turn is at a minimum.

The per cent of voltage drop through the reactance, *IX*, varies with the square of the number of turns, the thickness and length of the coils, and the spacing of the windings. The turns for an economical flux density and for a reasonable magnetizing current are fixed. However, the reactance can be greatly reduced by interleaving the windings. The noninterleaved transformer has approximately three times the reactance of the interleaved winding. In addition, interleaving assures the equal division of current in dual winding primaries operating in parallel. Another method to improve the regulation is to use a larger core than is required to meet the temperature requirements. This results in a lower reactance as the turns can be reduced in proportion to the increase in area.

The factors affecting the size of the transformer are the continuous load current required, the inrush current required, the power factor of the inrush current, and the minimum voltage required for the attached devices to operate.

When the time that the inrush current exists is less than 20 per cent of the total time, the full load current will determine the heating of the transformer. The continuous load current should not exceed the rated full load current of a transformer, as shown in Table I. Where the inrush time is an appreciable part of the total time, the equivalent full load current should be calculated by the following formula

$$\text{Equivalent full load amperes} = \sqrt{\frac{(\text{amperes inrush})^2 \times \text{time} + (\text{load amperes})^2 \times \text{time}}{\text{time for 1 cycle}}}$$

As a general rule, the temperature rise is not the limiting factor in choosing a transformer. The limiting factor is the minimum secondary voltage acceptable during the inrush period. The poorest regulation occurs at the point where the load power factor equals the impedance power factor of the transformer. For a well-designed interleaved transformer, the impedance power factor is nearly unity. As a result, a regulation curve drawn for a 100 per cent power factor load is very pessimistic. As a matter of fact, it has little significance, inasmuch as a 100 per cent power factor load, being of a resistive nature, has no inrush current other

Paper 50-217, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Oklahoma, October 23–27, 1950. Manuscript submitted September 30, 1948; made available for printing August 11, 1950.

JEROME M. FRANK and A. J. HAUCK are both with Hevi Duty Electric Company, Milwaukee, Wis.

Table I. Primary Voltage 600 or Lower Secondary Voltage 115

Kva	Rated Full Load Amperes at 115 Volts	60 Cycles %IR at 75° C	60 Cycles %IX	50 Cycles %IR at 75° C	50 Cycles %IX	Remarks
1/4	2.17	7.0	3.0	7.0	2.5	Not interleaved
1/3	4.35	3.3	0.6	3.3	0.5	Interleaved
3/4	6.52	2.8	0.6	2.8	0.5	Interleaved
1	8.70	2.8	0.7	2.8	0.6	Interleaved
1 1/2	13.05	2.0	0.6	2.0	0.5	Interleaved
2	17.40	2.2	0.7	2.2	0.6	Interleaved

than the steady-state value. The 100 per cent power factor curve is shown on Figures 1 and 2, inasmuch as it has been a practice among transformer manufacturers to show this curve. The most common power factor encountered, where control circuit transformers are used, is approximately 20 per cent. As a result, the curves of Figure 1 and Figure 2 show the regulation for 20 per cent power factor, for both 60 and 50 cycles. In all cases the 50-cycle curve indicates better regulation than the 60-cycle curve because of the decrease in reactance on 50 cycles. With the exception of the 1/4 kva, where space limitations make it very difficult to interleave, the per cent IX is approximately one-third the per cent IR. As a result, the regulation at low power factors is very good. The regulation at any power factor can be found by the equation given in the Standard Handbook for Electrical Engineers[1] as follows:

"Regulation in per cent

$$=\left[mr+nx+\frac{(mx-nr)^2}{200}\right] \text{ at rated load}$$

where

m = power factor of load ($\cos\theta$)
n = reactive factor of load ($\sin\theta$)
θ = angle of lag
r = per cent IR at 75 degrees centigrade
x = per cent IX."

Where the inrush current is six times rated current, the per cent regulation is approximately six times as great.

The fact that the regulation curves are drawn to 1,000 per cent load in some cases, does not indicate that the transformer can carry more than rated load continuously.

In order to use the regulation curves, the maximum sealed and inrush current that exists at any one time must be found and the approximate load power factor calculated. Choosing a regulation curve where the rated full load current is slightly larger than the required continuous current, the intersection of a line drawn at the value of maximum current encountered at any instant and the curve gives the value of the transformer secondary voltage at the time the maximum current occurs.

Since good regulation is the prime requisite for a control transformer, the methods of measurement to secure the data required for the regulation curves is of interest. The impedance of the transformer is effectively in series with the load and, therefore, reduces the current flow through it. The measurement of impedance is quite simple if a quantitative knowledge of its components is not required. A rms responsive voltmeter and ammeter will suffice to measure it. To determine the regulation at any power factor, we must know the value of its components, namely the reactance and the effective resistance.

The method generally employed for determining the reactance and resistance components of an impedance makes use of a wattmeter, voltmeter, and ammeter. The circuit is shown in Figure 3. It is generally agreed that the determination of the circuit parameters in low power factor circuits by this method is complicated by corrections due to phase angle errors in the current transformer and in the potential circuit of the wattmeter. What is not generally appreciated is the limitation of this method in determining the reactance in high power factor circuits. An example will illustrate this shortcoming.

1. Assume a 10-kva 1,000-volt transformer and an ammeter reading of 10 amperes, a voltmeter reading of 30.5 volts, a wattmeter reading of 300 watts. Neglecting losses in the potential circuits: volt amperes = 305; watts = 300; reactive volt-amperes = $\sqrt{305^2-300^2}=55$; per cent $IR=3.0$; per cent $IX=0.55$.

2. If the losses in the potential circuits are taken into account corrected ammeter reading = 9.98 amperes; volts = 30.5 volts; corrected wattmeter reading = 299.4 watts; volt amperes = 304.39; reactive volt-amperes = 54.9; per cent $IR=2.99$ per cent; per cent $IX=0.549$.

For the foregoing set of conditions the potential circuit errors may be neglected without appreciably affecting the results.

3. Now assume that in (1) the ammeter reads 1/4 per cent high, voltmeter reads 1/4 per cent high, wattmeter reads 1/4 per cent low, then: actual volt-amperes = 303.475; actual watts = 300.75; volt-amperes = 40.5; per cent $IR=3.01$; per cent $IX=0.405$; and error in IX from (1) = 35 per cent.

The example shown assumes impedances having a low reactance-to-resistance ratio. Control Transformers have been furnished in which the reactance-to-resistance ratio is even lower than the case cited. One remedy for the shortcoming cited involves the use of a reactive-volt-ampere meter instead of a wattmeter, so that the reactance component can be measured directly. One aspect of the case cited is favorable to the use of wattmeters and varmeters, namely the 30.5 volts drop across the impedance. Many control transformers have a high-voltage rating of 220 volts. The voltage drop across this winding would not exceed 6 or 7 volts for an impedance test. This voltage is too low to produce a reasonable scale deflection on commercially available wattmeters and varmeters. We have so far avoided mention of reading errors and the difficulty of reading three instruments under fluctuating voltage supply conditions. When these additional factors are taken into account, the results obtained are of doubtful accuracy.

Several null methods have been devised for determining the reactance and resistance components of an impedance. Most of these methods permit balance in spite of supply voltage fluctuations. Some of these methods permit the use of phase selective detectors so that independent balance of reactance and resistance com-

Figure 1. Regulation curve for 0.25 kva single-phase transformer, winding not interleaved

Figure 2 (left). Regulation curve for 0.5 kva single-phase transformer, winding interleaved

Figure 3 (above). Impedance measurement with wattmeter

Figure 5. 0.5 kva transformer

ponents is possible. The circuit employed to measure the characteristics of the control transformers has both of these valuable features.

Referring to Figure 4, a current I_1 flows through the primary of current transformer T and impedance $\boldsymbol{Z}=r+jx$, causing a voltage drop $\boldsymbol{E}_z=E_r+jE_x$ across this impedance. A current I_2 flows through the secondary of the current transformer, the primary of the mutual inductor M and the adjustable resistor R. By adjustment of M and R, voltages E_z and E_r can be made equal in magnitude and phase. This condition, indicated by zero response of the detector, results when $jE_m=jE_x$ and $E_R=E_r$. Knowing the ratio of the current transformer, we can write

$r=$ R/ratio of current transformer
$x=WM$/ratio of current transformer

where $W=6.28\times$frequency

Balance is quickly obtained because the detector circuit is phased to respond only to the circuit being adjusted. Wide fluctuations in supply voltage do not retard the balancing procedure nor affect the dial settings for the null points. The time consumed in making the measurement does not exceed that required for conventional methods. A single operator can determine the circuit parameters with an accuracy of approximately 1 per cent and can compute the results in a fraction of the time required for methods involving square roots.

This circuit is useful for measuring linear impedances ranging from $0.0001+j0.003$ to $0.1+j0.08$ ohms without drawing any current from the impedance under test. A potential divider interposed between the impedance and the detector circuit increases the range to $30+j24$ ohms. The maximum error introduced by the shunting effect of the potential divider is 1/10 per cent. It is apparent that this circuit is more suitable than the standard ammeter-voltmeter-wattmeter method for measuring the components of a linear impedance.

Adoption of this null method for determining the impedance characteristics of control transformers has made it possible to furnish reliable regulation curves. The accuracy obtained in the measurement of the reactance is especially important since the regulation at low power factor loads depends largely on this component of transformer impedance.

The factors affecting the cost of a transformer are the kilovolt-ampere rating, the quantity involved, the number of additional taps involved, the primary voltage, and the insulation required. High-voltage primaries (above 600 volts) require special insulation and are not interleaved as a rule, due to the necessity of maintaining a high insulation level between the primary winding and the secondary and core. Special insulation for tropical service or high ambient conditions requires special impregnation and wire.

Several groups are trying, at the present time, to standardize control transformer ratings, performance, and size but due to many diversified load and size requirements the attempt has not as yet been successful.

In choosing a control transformer, consideration must be given to the continuous full load current required and the regulation required. Choosing a transformer with interleaved windings insures good regulation at power factors in the operating range.

Integral Controller for Use in Carrier-Type Servomechanisms

R. L. COSGRIFF
ASSOCIATE AIEE

Synopsis: This paper presents an analysis and characteristics of a 2-phase induction motor system which may be used as an a-c integral controller in servomechanism designs or as an a-c integrator. The control phase winding of the motor is excited by a nonlinear amplifier in such a manner that the rotor acceleration is nearly proportional to the input voltage, and the output voltage, derived from the output of an a-c tachometer driven by the motor, is nearly proportional to the time integral of the input voltage. The inherent range and accuracy of the motor-tachometer combination as an integrator are substantially increased by the use of the nonlinear amplifier which linearizes the speed-torque characteristics of the 2-phase induction motor.

THE purpose of an integral controller in a servo system is to reduce the steady-state error of the system without greatly impairing the transient response.[1,2] An integral controller for the d-c systems fulfilling the above requirements usually consists of a simple resistance-capacitance network; however, integral controllers for a-c systems are more complex and are usually a source of trouble. One well-known type of a-c integral controller consists of a very narrow bandpass filter, tuned to the carrier frequency, which usually occurs in the form of a bridged-T or parallel-T network in the feedback circuit of an amplifier.[2,3,4] Unfortunately, a small change in carrier frequency renders this type of controller useless. Another method often used is to convert the a-c signal voltage into a direct voltage, allowing a d-c network to perform the integral operation, and then to reconvert the resulting d-c signal to the carrier frequency level.[5,7] This latter type, although insensitive to carrier frequency changes, is far from ideal due to the drift of the phase-sensitive detector and modulator, and the filtering problem in the output of the detector.

Because of the limitations of the conventional a-c integral controllers now in use, an investigation was made of several electromechanical devices which might be used as integral controllers. One of the more successful types studied was the 2-phase inertia motor controller described herein.

In this particular type controller or integrator, the rotors of a 2-phase motor and tachometer, together with two steel inertia disks, are mounted on a common shaft, the entire assembly being supported by an air bearing formed by introducing air flow in the motor airgap. Since the surfaces between the rotor and rotor housing are separated by a layer of air, the friction of the rotor assembly is small and for all practical purposes entirely viscous in nature. This allows the rotor to go through zero speed without the error caused by static and Coulomb friction.

The block diagram showing the method used to excite the motor is given in Figure 1. The current in the fixed phase of the motor is held constant at all times by the fixed-phase amplifier. The current in the control phase of the motor is proportional to the sum of the input signal which is to be integrated and the compensating signal which overcomes the effects of the viscous friction and nonlinearities of the motor. This compensating signal is derived from the output of the nonlinear amplifier which amplifies the output voltage of the tachometer. The gain of the nonlinear amplifier is controlled by the absolute magnitude of the current in the control winding.

When the system described is in operation, the effects of the viscous friction between the rotor and rotor housing and the effects of the nonlinear speed-torque characteristics are minimized, and the acceleration of the rotor is then nearly proportional to the input voltage. The voltage developed at the output terminals of the a-c tachometer is proportional to the angular velocity of the rotor assembly. Since the velocity of the rotor assembly is the time integral of the rotor acceleration, the voltage developed by the tachometer is proportional to the time integral of the input voltage.

Analysis

The exact speed-torque equation of the 2-phase motor is rather complicated.

This paper is based on work done at the Airplane Division of the Curtiss-Wright Corporation for the Air Forces. This material was also used by the author as a Master's Thesis at the Ohio State University. The author is indebted to Dr. E. H. Gamble, J. R. Campbell, R. Geiger, and W. Horton of the Curtiss-Wright Corporation and Prof. C. E. Warren of the Ohio State University for their helpful guidance and assistance.

Figure 2. Speed torque curves of 2-phase drag cup motor

However, when the effective rotor resistance is ten or more times larger than the sum of the effective rotor leakage reactance and the mutual impedance representing the coupling between the stator winding and rotor conductors, the relationship between the torque T and speed $d\theta_m/dt$ may be simply expressed by (see Appendix I)

$$T = K\left(\omega_0 I_x I_y - \frac{I_x^2 + I_y^2}{2}\frac{d\theta_m}{dt}\right) \tag{1}$$

where

K = a function of the impedance elements and is constant for a given carrier frequency
ω_0 = synchronous speed of motor
I_x = current in the control winding of motor
I_y = current in the fixed-excited winding of motor

In equation 1 it is assumed that I_x and I_y are in time quadrature.

The speed-torque curves for the actual motor used in the present investigation are shown in Figure 2, while ideal curves are shown in Figure 3.

The developed torque, as given by equation 1, accelerates the rotor assembly and opposes the reaction torque due to the friction between the rotor assembly and the rotor housing. If the moment of inertia of this rotor assembly is represented by J and the coefficient of viscous friction by f, then the equation of motion of the rotor assembly may be written

$$J\frac{d^2\theta_m}{dt^2} + \left[f + \frac{K}{2}(I_x^2 + I_y^2)\right]\frac{d\theta_m}{dt} = KI_xI_y\omega_0 \tag{2}$$

The fixed phase current I_y is equal to the product of the oscillator voltage E_y and the gain G_2 of the fixed phase amplifier, that is

$$I_y = G_2E_y \tag{3}$$

The control-phase signal I_x consists of two components: the input signal I_a which is to be integrated and the velocity feedback component $FE_v d\theta_m/dt$. The function F is not a constant, but is a function which must be generated in a manner presently to be explained to overcome the nonlinearity of the motor damping. Let G_0 be the gain of the control-phase amplifier. Then

$$I_x = G_0\left(I_a + FE_v\frac{d\theta_m}{dt}\right) \tag{4}$$

Assume that the function F is

$$F = G_1(1 + \beta I_x^2) \tag{5}$$

where G_1 and β are constants. It now will be shown that a proper choice of G_1 and β will make the system linear within certain limits. It is to be noted that the gain of the nonlinear feedback amplifier is determined by $|I_x|$.

To simplify the computations, let

$$A_1 = G_1E_v\frac{d\theta_m}{dt}G_0 \tag{6}$$

Substituting equation 5 into equation 4 and using equation 6 yields

$$\beta A_1 I_x^3 - I_x + A_1 + G_0I_a = 0 \tag{7}$$

from which

$$I_x = \frac{1 - \sqrt{1 - 4(I_aG_0 + A_1)\beta A_1}}{2A_1\beta} \tag{8}$$

By substituting the values of I_x and I_y, expressed by equations 3 and 8 respectively, into the system equation 2, the equation of motion becomes

$$J\frac{d^2\theta_m}{dt^2} + \left[f + \frac{K}{2}\left(G_2^2E_y^2 - \frac{1}{\beta}\right)\right]\frac{d\theta_m}{dt} = \frac{I_aK}{2G_1E_y\beta} + K\left[\frac{1 - \sqrt{1 - 4(I_aG_0 + A_1)A_1\beta}}{2G_1E_y\frac{d\theta_m}{dt}G_0\beta}\right]\left[\omega_0G_2E_y - \frac{1}{2\beta G_1E_yG_0}\right] \tag{9}$$

Now if

$$\frac{1}{\beta} = \frac{2f}{K} + G_2^2E_y^2 \tag{10}$$

Figure 3. Ideal speed torque curves of 2-phase motor

Figure 4. Nonlinear feedback circuit

and

$$\omega_0G_2E_y = \frac{1}{2G_1E_y\beta G_0} \tag{11}$$

then equation 9 simplifies to

$$J\frac{d^2\theta_m}{dt^2} = \frac{I_aK}{2G_1E_y\beta} \tag{12}$$

which is the equation desired, since both the angular velocity of the rotor and the voltage output of the tachometer are proportional to the time integral of the input signal I_a. It should be noted that any desired linear coefficient of viscous friction, positive or negative, may be effectively obtained by a proper choice of β.

The values of I_x, I_a, and $d\theta_m/dt$ all have upper limits which may not be exceeded for proper operation. The upper limit of $d\theta_m/dt$ is ω_0, the synchronous speed of the motor, and cannot of course be exceeded. However, it is physically possible for both I_x and I_a to exceed their limits. If the value of I_a exceeds its limit, then the value of I_x expressed by equation 8 becomes a complex quantity. The maximum real value of I_x as obtained from equation 8 is

$$I_{x\max} = \frac{1}{2A_1\beta} \tag{13}$$

Substituting the values for A_1 and β obtained from equations 6 and 11, respectively, and replacing G_2E_y by I_y, equation 13 reduces to

$$\frac{I_{x\max}}{I_y} = \frac{\omega_0}{d\theta_m/dt} \tag{14}$$

If the maximum value of I_x is exceeded, the nonlinear amplifier becomes unstable. The unstable nature of the feedback amplifier is evident from an inspection of Figure 4. As I_x becomes large the gain of nonlinear amplifier also becomes large and the amplifier under such condition is similar to a regenerative feedback amplifier. The point of instability as given by equation 14 may also be obtained by taking the partial derivative of I_x with respect to I_a and solving for I_x when this partial derivative is infinite.

Figure 5. Controlled phase feedback amplifier

Figure 6. Nonlinear amplifier and summing network

Tachometer

The a-c tachometer used is quite as important to the operation of the system as the motor itself.[6] A drag-cup type tachometer is used which has a very low output voltage level when the rotor is stationary. If the tachometer is to be linear, it is necessary that the leakage reactance and the resistance of the excited stator winding be made as small as possible in comparison with the value of the rotor resistance. The design parameters governing tachometer performance are discussed in Appendix II.

Electronic Equipment

The two amplifiers used to drive the two phases of the motor are conventional amplifiers with a large amount of current feedback, so that the current in each phase of the motor is proportional to the input voltage to the amplifier, see Figure 5.

As shown in Figure 6, the tachometer amplifier actually consists of two amplifiers, the outputs of which are added in a summing network. One amplifier has a fixed gain. The second amplifier consists of two pentodes both biased by a voltage proportional to the absolute value of I_x. This voltage is obtained from a rectifier which converts the absolute value of an alternating voltage proportional to I_x into a positive direct voltage. If this d-c bias is denoted by e, then the following power series for the gain G of the pentode stage may be written,

$$G = g_0 + g_1 e + g_2 e^2 + g_3 e^3 \ldots \tag{15}$$

By proper adjustment of the cathode resistance and the plate and screen voltages it is possible for the value of G to become approximately

$$G \approx g_0 + g_2 e^2 \tag{16}$$

A plot of $G - g_0$ versus e is shown in Figure 7, together with an ideal curve.

If equation 16 holds, then the gain of the tachometer amplifier will consist of two components. One component of the gain will be constant while the second component will be proportional to e^2 and consequently I_x^2. By adjusting the magnitude of these two components the gain of the tachometer amplifier can be made to approach the value of F required by equation 5.

Operation of the Controller

The operating characteristics of the controller are better in many respects than the conventional a-c integral controllers. For example, the equivalent bandpass filter used as an integral controller would have a Q of over a 10^6 at 400 cycles. This corresponds to a pass band of less than one cycle per hour. The ratio of maximum velocity to minimum velocity of the described controller is over 8×10^3 and may be increased by balancing the rotor mechanically. The velocity range is greater if the region of improper compensation is also considered. A typical response of the system to a step function is shown in Figure 8.

It is very difficult to adjust the amplifier to obtain the accuracy mentioned, and changes in the frequency of the oscillator voltage necessitates readjustment of the amplifier. The effect of the frequency change is to introduce a friction term in equation 12. However, it has been found possible to eliminate this source of trouble by allowing the gain of the tachometer amplifier to decrease at a rate of 6 decibels per octave in the region of operation.

Simplified Motor Integral Controller

The rotor resistance of a 2-phase induction motor may be adjusted so that the speed-torque curves, plotted in a manner similar to those shown in Figures 2 and 3, are nearly vertical as the rotor velocity approaches zero. At speeds less than 30 per cent of synchronous speed the acceleration of the rotor of such a motor is nearly proportional to the input signal. Since the back electromotive force is nearly proportional to the velocity of the rotor, this voltage may be used for the output signal. This may be done by arranging the motor in a bridge circuit as shown in Figure 9.

The input impedance of the motor with a blocked rotor may be made real by adding a condenser in series or in parallel with the motor. By adjusting R until it is equal to this blocked rotor input impedance the output voltage at standstill will be zero, and the developed voltage at this output terminal will be nearly proportional to the angular velocity of the rotor. Likewise the driving voltage at the output of the amplifier will be proportional to the amplifier input voltage plus a component proportional to the rotor velocity. Thus the integral control signal may be obtained directly from the output terminals of the amplifier if desired. The characteristics of this controller may be

Figure 7. Compensated amplifier gain

Figure 8 (left). Typical response of the controller to a step function

Figure 9 (right). Simplified motor integral controller

changed by the use of voltage and current feedback in the amplifier.

Conclusions

The performance of the compensated integral controller described is very much better than is usually required for most servo systems. In fact, as has been pointed out, the controller is actually an excellent integrator. Since the effects of oscillator frequency shift, originally a limitation of the controller, may be largely eliminated, it appears that the ultimate limitation of the device depends upon the accuracy with which the gain as required by equation 11 may be approximated, and upon the drift of the amplifier used to obtain this gain.

The controller may be simplified in several ways for practical applications. For example, a good mechanical bearing of conventional design can be substituted for the air bearing. Furthermore, the fixed phase may be excited directly from the source voltage. Even the simplest version which requires no tachometer is sufficient for the control of many servo systems.

Appendix I. Derivation of Motor Equation

The speed-torque relationship for a 2 phase induction motor in terms of the current flowing in each winding is given by equation 110 of reference 5. This equation is

$$T' = (I_x^2 + a^2 I_y^2)(R_f - R_b) + 2aI_xI_y(R_f + R_b) \sin\phi \quad (17)$$

where

T' = average developed torque in synchronous watts

I_x = rms current flowing in the controlled phase

I_y = rms current flowing in the fixed phase

a = turns ratio of the x and y stator windings

ϕ = phase shift between I_x and I_y

If $\phi = \pi/2$ and $a = 1$, equation 17 becomes

$$T' = (I_x^2 + I_y^2)(R_f - R_b) + 2I_xI_y(R_f + R_b) \quad (18)$$

The values of R_f and R_b are given by equations 54 and 57 of reference 5 and are

$$R_f = \frac{X_m^2 R_2 S}{R_2^2 + S^2(X_2 + X_m)^2}$$

$$R_b = \frac{X_m^2 R_2 (2-S)}{R_2^2 + (2-S)^2(X_2 + X_m)^2} \quad (19)$$

where

X_m = coupling reactance between the stator winding and the rotor conductor

R_2 = effective rotor resistance referred to the stator winding

X_2 = effective rotor leakage reactance referred to the stator winding

S = slip of the motor

When a 2-phase motor is used for control purposes it is convenient to use α, the ratio of motor speed to synchronous speed, as the variable instead of the slip S. The value of S in terms of α is simply

$$S = 1 - \alpha \quad (20)$$

Let

$$\xi = \frac{X_2 + X_m}{R_2} \quad (21)$$

Then equations 19 may be written

$$R_f = \frac{X_m^2}{R_2}\left[\frac{1-\alpha}{1+(1-\alpha)^2\xi^2}\right]$$

$$R_b = \frac{X_m^2}{R_2}\left[\frac{1+\alpha}{1+(1+\alpha)^2\xi^2}\right] \quad (22)$$

Using equations 22 the values of $R_f + R_b$ and $R_f - R_b$ may be easily shown to be

$$R_f + R_b = \frac{2X_m^2}{R_2} \cdot \frac{1+(1-\alpha^2)\xi^2}{[1+(1-\alpha)^2\xi^2][1+(1+\alpha)^2\xi^2]}$$

$$R_f - R_b = -\frac{2X_m^2}{R_2} \cdot \frac{\alpha[1-(1-\alpha^2)\xi^2]}{[1+(1-\alpha)^2\xi^2][1+(1+\alpha)^2\xi^2]} \quad (23)$$

Putting equations 23 in equation 18 yields

$$T' = \frac{2X_m^2}{R_2} \cdot \frac{-\alpha(I_x^2 + I_y^2)[1-(1-\alpha^2)\xi^2] + 2I_xI_y[1+(1-\alpha^2)\xi^2]}{[1+(1-\alpha)^2\xi^2][1+(1+\alpha)^2\xi^2]} \quad (24)$$

Now

$$\lim_{\xi \to 0} T' = \frac{2X_m^2}{R_2}[-\alpha(I_x^2 + I_y^2) + 2IxIy] = T \quad (25)$$

When I_x is equal to I_y the error ratio de-

Figure 10. Equivalent circuit of 2-phase motor with nonlinear elements

fined as $(T'-T)/T$ may be readily shown to be

$$\frac{T'-T}{T}=-\xi^2(1-\alpha)^2 \tag{26}$$

in which terms in ξ^4 have been neglected. Equation 26 shows that the approximate value T is very nearly equal to the actual torque T' when $\xi \leq 0.1$. For small values of ξ then, the developed torque becomes

$$T=K\left[-\frac{d\theta_m}{dt}\frac{(I_x^2+I_y^2)}{2}+\omega_0 I_x I_y\right] \tag{27}$$

which is equation 1.

Appendix II. A-C Tachometer Characteristics

The equivalent circuit of a 2-phase motor shown in Figure 10 may be found in reference 7. From this equivalent circuit the following set of equations may be derived.

$$\begin{aligned}
e_x &= Z_{11}i_{1x}+Z_{13}i_{2x}\\
e_y &= Z_{11}i_{1y}+Z_{13}i_{2y}\\
0 &= Z_{13}i_{1x}+Z_{22}i_{2x}-\alpha[Z_{13}i_{1y}+(Z_{22}-R_2)i_{2y}]\\
0 &= Z_{13}i_{1y}+Z_{22}i_{2y}-\alpha[Z_{13}i_{1x}+(Z_{22}-R_2)i_{2x}]
\end{aligned} \tag{28}$$

In these equations the impedances are defined as

$$\begin{aligned}
Z_{11} &= R_1+j\omega L_{11}\\
Z_{13} &= j\omega L_{13}\\
Z_{22} &= R_2+j\omega L_{22}
\end{aligned} \tag{29}$$

where

R_1 = resistance of each stator winding
L_{11} = sum of the stator leakage reactance and L_{13}
L_{13} = mutual reactance coupling the stator winding to rotor conductors
L_{22} = sum of the rotor leakage reactance and L_{13}
R_2 = equivalent rotor resistance referred to the stator winding

and the voltages and currents are defined as

i_{1x} = stator current in the x-phase
i_{2x} = rotor current in the x-phase referred to the stator winding
i_{1y} = stator current in the y-phase
i_{2y} = rotor current in the y-phase referred to the stator winding
e_x = terminal voltage of the x-phase
e_y = terminal voltage of the y-phase
α = ratio of rotor speed to rotor synchronous speed

The open-circuit voltage developed at the terminals of y-stator phase now will be found. Since for this condition i_{1y} is zero, the value of e_y becomes from the second of equations 28

$$e_y=Z_{13}i_{2y} \tag{30}$$

Solving the first, third and fourth of equations 28 simultaneously for i_{2y} yields

$$i_{2y}=\frac{\begin{vmatrix} Z_{11} & Z_{13} & ex\\ Z_{13} & Z_{22} & 0\\ -\alpha Z_{13} & -\alpha(Z_{22}-R_2) & 0\end{vmatrix}}{\begin{vmatrix} Z_{11} & Z_{13} & 0\\ Z_{13} & Z_{22} & -\alpha(Z_{22}-R_2)\\ -\alpha Z_{13} & -\alpha(Z_{22}-R_2) & Z_{22}\end{vmatrix}} \tag{31}$$

which when expanded and substituted in equation 30 gives

$$e_y=\frac{-\alpha Z_{13}^2R_2e_x}{\alpha^2[Z_{13}^2-Z_{11}(Z_{22}-R_2)](Z_{22}-R_2)+Z_{22}(Z_{11}Z_{22}-Z_{13}^2)} \tag{32}$$

Since in the derivation of the equivalent circuit all voltages and currents having a "y" subscript lead the actual values by $\pi/2$ radians, the voltage e_y is leading the actual voltage at the output of the tachometer by $\pi/2$ radians.

The effects of α^3 in the denominator must be minimized if the output of the tachometer is to be linear. This can be done by reducing the impedance ratio

$$R_a=\frac{Z_{11}Z_{22}-Z_{13}^2-R_2Z_{11}}{Z_{11}Z_{22}-Z_{13}^2} \tag{33}$$

to as small a value as possible. If

$$Z_{11}=Z_{13}$$

and

$$Z_{22}=R_2+Z_{13}$$

then R_a becomes zero as desired. This means that the stator winding resistance and the leakage reactance of the rotor and stator should be made as small as possible. Likewise if R_2 is much larger than Z_{13}, the same effect will be obtained.

Single-Phase Power Transformer Formed Cores

T. D. GORDY
MEMBER AIEE

G. G. SOMERVILLE
MEMBER AIEE

Synopsis: For many years power and distribution transformer cores were built of hot-rolled laminations assembled into a core structure. When cold-rolled, oriented strip steel was introduced into transformers, new types of distribution transformer cores were developed. These cores were of the wound type and utilized the magnetic properties of oriented steel very efficiently. Recently, a new type of single-phase power transformer core using oriented steel has been developed and put into production. A description of the design, manufacture, and characteristics of this new core is given. Power transformers with this type of core built by the General Electric Company are designated Spirakore transformers.

STEELS FOR magnetic circuits have been improved in many ways during the years of transformer improvement. Lower core loss, lower exciting current, improved mechanical properties, and non-aging characteristics are but a few of the improvements that have been made on the steel. However, until the introduction of highly oriented, cold-rolled steel, essentially all distribution and power transformer cores were built by stacking rectangular, L-shaped, or E- and I-shaped laminations into a core structure.

In order to utilize better the improved magnetic characteristics of this new steel, a wound core was developed for distribution transformers.[1] Even though this type of core had good magnetic characteristics, it was limited to distribution transformer sizes. Weight, size, and mechanical requirements of cores used in power transformers prevented its use in these sizes. In order to obtain characteristics similar to the wound-core distribution transformer, a new type of precut-preformed, single-phase core for use in power transformers has been developed and put into production in sizes up to and including 3,333 kva. This paper discusses the characteristics of oriented cold-rolled steel and the development of the Spirakore for use in power transformers.

Properties of Material

Nonlinearity between flux density and magnetizing force is a characteristic of all steels used in power transformer cores. In addition, highly oriented, cold-rolled steel has more important characteristics that must be considered if it is to be used efficiently in power transformer cores.

Directional Characteristics

Cold-rolled steel is produced in continuous strips or bandwidths, while hot-rolled material is produced in sheet form. With certain composition, working, and processing, highly directional magnetic properties may be obtained. A large proportion of the crystals are oriented so that an easy direction of magnetization is parallel to the rolling direction. In such material, when the flux passes through the lamination in a direction parallel to the direction of rolling, low core loss is obtained, and a low magnetizing force is required. If flux is caused to pass through such steel in directions other than one parallel to the rolling direction, core loss and magnetizing force are increased. The amounts which these quantities increase depend upon the flux density. Figure 1 illustrates the variation of core loss with the direction in which flux passes through such steel for three different flux densities. Figure 2 illustrates the variation of magnetizing force with the direction in which flux passes through the steel for three different flux densities.

Magnetic characteristic variations, shown in Figures 1 and 2, show why it is important to use oriented cold-rolled steel in transformer cores so that flux passes through the steel in the direction of rolling. Not only may the lowest possible core loss and exciting current be obtained, but also minimum flux distortion will result.

Strain Effects

Oriented cold-rolled transformer core steel is much more sensitive to mechanical strain than is hot-rolled core steel. Both core loss and magnetizing force are increased as strain is increased. Because of this strain-loss relation, strain in the core structure must be seriously considered and minimized.

Core steel may be strained and formed into any desired shape before final anneal; but after anneal, the steel should be maintained in its annealed form for minimum core loss and magnetizing force. Therefore, in a core structure, core steel should be supported and clamped such that it is kept in the same form in which it was annealed.

General Design of Core Structure

Aside from using oriented cold-rolled steel such that flux passes through it in a direction parallel to the rolling direction, other fundamental functions of the core must be achieved. In designs using cylindrical windings, core cross section inside the winding circle should approach a circle. Heat generated in the magnetic circuit must be efficiently transmitted to the cooling liquid. Lifting, shipping, and short-circuit forces must be transmitted or withstood by the core and clamp structure. These requirements are fulfilled by this type of core.

Paper 50-220, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 24, 1950; made available for printing August 21, 1950.

Figure 1 (left). Variation of core loss with angle from rolling direction of steel

Figure 3 (right). General arrangement of core quarter-sections and cross sections

Core Cross Section

It has been shown that for a given number of widths of steel to be built into a core cross section approaching a circle, certain widths and builds of packets will give a maximum cross-sectional area.[1,3] Theoretical optimum cross-section dimensions are first determined. These dimensions may be modified slightly to permit use of stocked steel widths on a line of core sizes and to allow for bolts, tie-bars, and tie-plates. These modifications do not reduce the cross-sectional area appreciably from the theoretical optimum area. Some form of bolting, bonding, or tie-barring is required if a high space factor of iron is to be obtained. Several widths of steel are used in any one core design, depending on the rating. The core has been divided into four quarters; quarters have been clamped in the center leg by insulated tie-plates and tie-bars, as shown in Figure 3. Outside legs are secured by angled plates which are a part of the clamp.

Not only does this arrangement afford efficient utilization of the available iron space, but it gives step-backs in the yokes at the tops and bottoms of the windows into which adjustable coil support brackets may be fitted.

Figure 2 (left). Variation of magnetizing force per-unit length with angle from rolling direction of steel

Core Form

To maintain the desirable magnetic characteristics of the wound-type, cold-rolled steel core, the precut-preformed method was developed. This core, as applied in most Spirakore power transformers up to 3,333 kva, has one joint per lamination convolution. Joints are staggered in the joint region of Figure 3 such that a stepped joint having small overlap is obtained.

Starting with the lamination convolution forming one of the windows and progressing outward through the build of the core, lengths of the strips will increase linearly. Hence, if the core be developed horizontally into straight laminations, stacked with one end of the laminations at a vertical reference, the laminations would appear as a trapezoid with a rectangular end. Such laminations are progressively cut by an automatic indexing shear. As sheets leave the shear, they are coated with a material which acts as a separator during annealing of the core and remains as an insulation coating to limit eddy currents between laminations during transformer operation.

As laminations leave the coating machine, they are stacked into a ring, then

Figure 4 (right). One-quarter of a single-phase Spirakore power transformer core

Figure 5 (left). Assembly of quarter cores into bottom clamps of a Spirakore power transformer

Figure 7 (right). Formed core with coils on center leg and part of laminations reassembled around coils

formed into the required rectangular-window shape. After anneal, a precut-preformed core which will maintain its formed shape is obtained. Figure 4 shows one-quarter of a Spirakore power transformer at this stage of its processing and demonstrates how the joints may be staggered and maintained in proper position in the magnetic circuit. All of the steel is utilized in the rolling direction, and no corner effects are introduced. Four such quarter cores are assembled into clamps as shown in Figure 5. In this figure, top clamps and clamp insulation are removed.

Figure 6. Assembly of core and clamps of power transformer; top clamps in place but not completely bolted

Clamps

The clamping structure should be such that little if any strain on the core is introduced. Also, the core must be insulated from the clamps so that the core may be grounded at one point only. Multiple grounds which would be obtained if the core were not insulated from the clamps would result in partial- or total-turn short circuits on the core. Even though clamps should not strain the core, they should secure the core firmly and leave space for ducts for oil flow to cool the core.

For this type of core, a clamping structure has been designed which will cradle the core and permit lifting. Figure 6 shows the core of Figure 5 with top clamps in place. Outer legs of the core are supported by the insulated outer vertical members of the clamping structure and insulated cross bars. The core is supported from the bottom by bottom cross bars auxiliary cradling straps, and blocks. Coil supports on the bottom clamps support the windings, and lifting and short-circuit forces are sustained by the clamping structure, not by the core. It will be shown later how adjustable top coil supports are attached to top clamps to maintain a tight coil stack.

Coil Assembly

Coils are placed on the center leg of the core by removing the top clamps, opening the joint, folding back the laminations, and then lowering the coil stacks into place. The laminations that are folded back must be supported in the folded-back position such that the elastic limit of the core steel is not exceeded; exceeding the elastic limit would increase core loss and exciting magnetomotive force.

Laminations are put back into place until all of the laminations are back in the position in which they were annealed. Bands around each quarter core help maintain closed joints and reduce noise level. This method of core building and assembly gives close-fitting joints which are necessary for low core loss, low exciting current, and low noise level.

Top clamps, top clamp insulation, cross bars, clamping bolts, and the adjustable coil supports are then added. Blocking immediately over the joint region further reinforces the joint for tightness. The core and coil assembly as shown in Figure 8 is then ready for cabling, treating, and tanking. The pierced tab extending from the left side of the core in Figure 8 is the core grounding strap. This strap is not bolted to the clamp until the core and coil structure has been treated so that the core may be tested for grounds when it is ready for final tanking.

Characteristics of Transformer

Effective utilization of oriented cold-rolled steel in the formed core is best measured by the characteristics of the com-

Figure 8. Formed core with coils completely clamped and ready for cabling

Figure 9 (left). Curves showing variation of core loss with per cent voltage

A. Formed core
B. Plate core with lapped joints
C. Plate core with mitered joints

pleted transformer built on this type of core. In Figures 9 and 10 are curves which show 60-cycle core loss and exciting current as functions of per cent rated voltage for a given transformer rating built on three different cold-rolled steel core designs. Curve A is for a design using the formed core as described in this paper. Curve B is for a design using rectangular-plate laminations and conventional lapped joints. Curve C is for a design using plate laminations and mitered joints.

The improvement in core characteristics resulting from the Spirakore construction is quite obvious. The core loss is reduced to 80 per cent, and the exciting current to 35 per cent of the values obtained with a core using plate laminations and lapped joints. The improvement from the use of mitered joints is appreciable but not as great as from the use of Spirakore construction.

Several factors account for these improvements in core loss and exciting current:

1. Flux passes through the core steel and joints in a direction parallel to the rolling direction of the steel.

2. Joint regions are a small part of the total magnetic circuit; thus, introduce very little reluctance in the magnetic circuit.

3. Strain effects on the core are reduced by cradling clamps around the core and not loading the core with coil weights and supporting forces.

4. Joints are closed and maintained tight by the clamping structure.

5. The core is annealed in its final form so that no assembly, piercing, forming, or shearing strains remain in the core.

Figure 10 (right). Curves showing variation of exciting current with per cent voltage

A. Formed core
B. Plate core with lapped joints
C. Plate core with mitered joints

Although the 3-leg 4-section, single-phase core has been described in this paper, similar 2-leg 2-section designs have been made and built. These designs may be built with either two or four joints per convolution, depending upon the particular design requirements.

Conclusions

Efficient and economical utilization of oriented cold-rolled steel requires that:

1. The magnetic flux traverses the steel in the rolling direction.

2. The effect of joints be reduced.

3. The strains in the finished core be minimized.

These requirements are fulfilled by the Spirakore design described in this paper. Reductions in core loss, exciting current, and noise level have been obtained and demonstrated; they are being realized in routine production units of this type.

No Discussion

Induced Currents in High-Capacity Bus Enclosures

S. C. KILLIAN
MEMBER AIEE

IN RECENT years the air-insulated high-capacity bus has come into wide use in central stations for connecting generator, high-tension transformer, and switchgear. Metal-enclosed to provide a grounded member between live conductor and station personnel and most often having interphase barriers to prevent phase-to-phase faults, these busses now are built in a variety of designs. Each has features to recommend it when considered from an economic, mechanical, structural, or electrical viewpoint. The electrical problem, much less evident than the others, centers about the enclosure rather than the conductor and involves the question of circulating currents in the enclosure.

These currents may be allowed to flow as in the unsegregated phase enclosure, Figure 1(A) and the segregated phase enclosure, Figure 1(B) where they will heat the enclosure but protect adjacent building steel from inductive and magnetic heating. In the isolated phase enclosure, Figure 1(C), it will be readily seen that enclosure currents cannot flow between phases. The individual phase ducts are also broken into sections by insulating strips which further reduce these currents. Heating in these enclosures will be small but adjacent steel will not be protected from inductive and magnetic heating. Other external means must then be used to keep the temperature of this steel at reasonable values.

Where circulating currents are allowed to flow in the enclosure, a careful choice of enclosure material must be made as this will determine the losses in the enclosure and the voltage drop in the main bus. This paper will discuss in the main those enclosures in which circulating currents are allowed to flow.

The induced currents in the enclosures of Figures 1(A) and 1(B) will be similar. For a simplified diagram of induced current flow in such an enclosure refer to Figure 2. Consider instantaneous current flow in the conductors to be as shown by the heavy arrows. The currents induced in the top and bottom sheets will then appear as shown by the dotted lines, and will flow so as to generate fields whose flux will oppose the field of the main conductor through as much duct length as possible. This requires the closing of these circuits in the very edges of the sheets as shown by the double-dotted lines. This end effect with its high current concentration produces a comparatively high temperature rise. It occurs in the laboratory when a heat run is made as shown in Figure 3 but not very often in practice. In almost all instances the bus duct will terminate on a generator casing, a transformer, or switchgear housing. In these cases the closing circulating current will flow in these various housings. Since these housings have a comparatively large mass, this current will produce a small temperature rise. On the other hand, the bus duct may terminate at a wall and the conductors continue through and then the higher rise due to end effect appears.

Current Distribution in the Duct and the Effects of Duct Length

In order to study the effects of current distribution and duct length, a mock duct was built of rods as shown in Figure 4. The network above and below the main conductors represents the top and bottom sheets of the duct while those beside the conductors represent the side walls and barriers. Circulating currents will be induced in these rods in a manner similar to that in continuous sheets. All branch currents are separate, however, and consequently lend themselves to measurement with a clip-on ammeter. Exact readings cannot be made but they are amply accurate for an investigation of this kind.

The current distribution in one of the ends of a mock duct test is shown in Figure 5. The over-all length of the grid was 10 feet 6 inches. Rods were 3/4-inch diameter copper. Other dimensions are shown in the figure. The current in the mains which were placed in the centers of the three sections was 2,500 amperes. The figures marked on the various network members are induced currents in amperes. Note how the currents distribute and close in rods "T" and "B" representing the bottom and top sheets of the duct. Although no near rods were used in this network parallel to bars "B" and "T", Figure 6 will show that even if close-by parallel paths are available, the greatest percentage of the current will still flow in the end conductors because of end effect.

All readings are given exactly as made. While care was taken to make up all joints in an identical manner, their resistances did vary somewhat. This accounts for the apparent small discrepancies in the diagram when it is analyzed. Note how the currents in rods "L", "M", "N", and "O", Figure 5, representing the side walls and barriers, divide almost perfectly; half of the current flowing into the bottom network and half into the top. The 100 amperes flowing up in the rod at the extreme left are joined by the 80 in the rod representing the corner of the duct. Their sum, 180, closely checks the 190 read. This 190 is joined by the 160 in the rod immediately above the conductor to produce 350, close to the 370

Paper 50-222, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23-27, 1950. Manuscript submitted March 13, 1950; made available for printing August 21, 1950.

S. C. KILLIAN is with the Delta-Star Electric Company, Chicago, Ill.

Figure 1. Enclosed bus configurations

read. Beyond this toward the center of the network, the currents close between phases and add vectorially. A similar check can be made on other sections of the grid.

In order that current distribution in the duct ends could be compared to all other points, the covers on top of the duct shown in Figure 3 were removed and replaced with the closely spaced network of rods shown in Figure 6. This network was insulated from the duct. Results would not, of course, be directly comparable to the grid shown in Figure 4 but do indicate what the relative current distribution would be. Furthermore, the time required to build a closely spaced grid completely around the main conductors, as in Figure 4, would be prohibitive. The current in the mains was 4,500 amperes. Grid currents are marked in amperes. The long rods were placed directly above the main conductors and parallel to them. Note that the current in these rods is consistent for the entire length of the grid. Note how quickly the current density falls off in the cross rods from the ends toward the center. Variations in joint resistivity account for the unequal current distribution in the "r" and "s" branches across the grid.

Another factor influencing current distribution to a small degree was the presence of the duct under the grid. Although the grid was insulated from the duct, the circulating currents in the duct affected those in the grid. Duct sections were split as shown in Figure 6 and entirely insulated from one another. This caused end effect currents in the duct and these in turn affected currents in the grid. This accounts for the somewhat disorderly progression from maximum currents in the grid ends to a minimum at the center.

The graph above the grid in Figure 6 plots average values read on rods "r" and "s" for each position across the grid. The curve plotted through these points is an average which would appear if all grid joint resistances were equal and the duct was not present under the grid. The actual readings and the curve are not far apart as can be noted from the figure. The curve forcefully pictures the large currents carried in the end members as compared to other members.

Figure 7 is a correlation of data in graph form for various lengths of networks similar to Figure 4. Maximum currents in rods "A", "B", and "C" as marked in Figure 4 are shown. It will be noted that for short lengths the circulating current increases rapidly with an increase in duct length. With further increases in duct length, this current increases much more slowly. The current in rod "B" was approximately the same as that in the other rods directly above and below the main conductors. Also the current in rod "C" was about the same as that in the other rods at the same elevation between phases.

As a further check on the relationship between duct length and maximum current and temperature rise, a setup as shown in Figure 8 was made. Here the duct is represented by a single sheet. The length of this sheet was varied. This is not a true picture of the actual duct since current contributions will be made from the side sheets and barriers. However, it does give a very good relative comparison. Currents were measured in the sheets by using a clip-on ammeter in the holes shown in the plates of Figure 8. This is not a perfect method of measuring maximum current but is sufficiently accurate for our purposes. Note the same general characteristic as obtained with rods—a steeply ascending curve, gradually flattening out. Temperature rises in the sheets also were taken on this series of tests and it is interesting to compare them with currents and note that they go hand-in-hand as would be expected. Temperature rises taken in the middle of the sheets at line C–C, as shown by the lower curve, were much lower than in the ends.

As still another check to determine what effect the bus duct length might have on temperature rise, an actual section of bus was tested. After temperature readings were taken on the 18-foot section of duct shown in Figure 3, the duct itself was divided electrically into three sections, 10-feet, 2-feet, and 6-feet long. Maximum rises in the ends of each section were close to one another and also to the maximum rise in the 18-foot section. This is about what would be expected from

Figure 2. Simplified diagram of induced current flow in enclosure

Figure 3. 5,000-ampere bus on test

Figure 4 (above). Study induced currents by means of mock duct

Figure 5 (right). Induced current flow in end section of mock duct

Figures 7 and 8 and from proximity effect in the adjacent sheet ends which is discussed in the following section.

This variety of tests definitely proves the desirability of connecting duct sections together electrically in order to avoid the appearance of end effects over and over at every joint. This is done by means of annular rings which protrude through holes in the gaskets where the sections join each other and are bolted together. Field tests on duct installations in powerhouses have verified the proficiency of this method and the absence of hot spots.

Comparative tests and values on an actual duct would likely be of interest. Figure 3 shows a 5,000-ampere dust-tight bus under test. Double-phase barriers are used and the entire duct structure is constructed of aluminum. The duct is 18 feet long. At 5,000 amperes the maximum rise in the duct ends was 42 degrees centigrade. This temperature was recorded at the end of the duct in the area marked with an "X" in Figure 2 and is concentrated in the end of the sheet. A very large temperature differential can be obtained if readings are taken only 2 inches from the end of the duct. All other points on the duct ran much cooler, rises of 19 to 23 degrees centigrade being in the big majority. Readings taken on this bus after it was installed in the powerhouse produced lower maximum rises. This is true because end effect currents close on switchgear of low resistance, producing smaller losses.

At 4,000 amperes the laboratory test of Figure 3 produced a maximum end rise of 31 degrees centigrade. At 3,000 amperes this rise was 17 degrees centigrade. A rise of 17 degrees centigrade is not high enough to cause concern and the electrical bonding between duct sections can

Figure 6. Induced current flow in closely spaced grid

Figure 7. Influence of grid length on induced current

be eliminated if so desired. Above 4,000 amperes, duct sections should be bonded.

Proximity Effect in Adjacent Bus Duct Sections

It would be expected that proximity effect has a bearing on the end effect when duct sections are insulated one from another, as in Figure 3. In order to test this directly, the setup of Figure 9 was constructed. The two sheets were separated or insulated from each other by 1/8 inch. From the grid test illustrated in Figure 6, we know that even in an isolated grid or sheet, the closing currents will concentrate to a very great extent in the ends of the grid or sheet. This condition is even further intensified by the proximity effect. Closing currents at lines A and B, Figure 9, will oppose one another. These opposition currents will generate fluxes which will oppose one another, and shift the fields of the two currents to points of maximum possible separation. This in turn locates maximum reactance at a maximum distance and maximum current at a minimum distance.

The values marked on the aluminum sheets of Figure 9 are temperature rises in the sheets with 5,000 amperes in the mains. Note that the maximum rise at line "C" closely checks the maximum rise for the 3 foot 6 inch sheet of Figure 8 and that the maximum rise at line "D" closely checks with the maximum rise for the 24-inch sheet of the same figure. The rise at line "A" however is 35 degrees as compared to 24 degrees at line "C", and 31 degrees at "B" compared to 24 degrees at "D". In all previous tests mentioned, sheets were tested alone or isolated from adjacent sheets by several feet and rises in both ends of the sheet were identical. This discrepancy, 11 degrees and 7 degrees, is due to proximity effect where the sheets almost touch each other. This shows that duct sections insulated from each other by thin material will heat more than sections tested alone and much more than sections bonded together electrically.

This also explains why the various sections of Figure 3—10 feet, 2 feet and 6 feet

Figure 8. Influence of sheet length on induced current

Figure 9. Influence of proximity effect on induced current

Figure 10. Influence of grid resistance on induced current

long—all insulated from each other, heated at their ends to about the same maximum as the full length 18-foot section. No proximity effect was present in the 18-foot test where a maximum rise of 42 degrees centigrade was found in the duct ends. Current crowding because of this effect in the split duct brought the rises up to about the same level. Maximum end rises are noted on Figure 3. It is of detail significance that the 10-foot free end ran 1 degree less than the 18-foot length while the end adjacent to the 2-foot section ran 2 degrees more. The 2-foot section, which should heat much less because of its short length, was exposed to proximity effects on both sides and ran 3 degrees and 6 degrees less than the 18-foot section at each end. The 6-foot section ran 2 degrees less at the adjacent end and 5 degrees less at the free end as compared to the 18-foot section. These values serve perfectly to check the heating relationships of short sections of duct as compared to long sections and the importance of proximity effect.

Enclosure Current versus Main Current

Many setups were made on various forms of grids and sheets with various main-conductor currents. The current in the grids or sheets was measured and it was found that, as would be expected, this induced current was in direct proportion to the main current for a given setup.

Phase spacings of main conductors also were varied. As taught by theory, it was found that decreasing phase spacing of the mains decreased the circulating current in a given sheet or grid.

Voltage and Impedance Characteristics of Enclosures and Main Conductors

The voltage induced in a bus duct when measured from one end to the other, parallel to the main conductor, is proportional to length. The induced open circuit voltage for the duct shown in Figure 3 was measured by removing the covers and stretching wires above each of the main conductors at the cover level. Maximum voltage measured was 1.3 volts over the 18 feet of duct with 5,000 amperes in the mains. The largest voltage read over the same setup, but with the covers in place and fully short circuited for the entire duct length, was 0.26 volt.

Voltages measured at right angles to the preceding showed maximum readings of 0.8 volt in the covers from a point directly above phase A to a point directly above phase C at the end of the duct. In the center of the length of the duct this voltage difference became zero. This voltage distribution over the duct when plotted against duct length results in a curve similar to Figure 6.

Since voltages induced in the duct are proportional to length and duct resistances are proportional to length, it would be thought that the current induced in the duct would be a constant if the reactance were proportional to length. This is almost true for longer lengths of duct but in the shorter ducts larger currents per foot of bus are induced as can be seen from Figures 7 and 8. Where duct lengths of only a few feet are considered, the coupling between all four sides of the induced circuit is so close that the reactance per foot of duct is small. This in turn makes for a smaller impedance and consequently a larger current. This factor quickly disappears however as the bus lengthens, see Figures 7 and 8, and the current almost becomes a constant, and independent of bus length.

All foregoing discussion in this paper has dealt with currents, voltages, and impedances of the enclosures. It is to be expected that the main conductor currents would be affected by the enclosure currents and such is the case. The flux of the induced enclosure current directly opposes that of the associated conductor, thereby reducing the net flux linking the main conductors. This reduces the reactance and decreases the voltage drop through the bus as compared to an unenclosed bus. This relationship has been carefully studied and verified for lead covered and armored cables.[1]

No attempt was made on this series of enclosure tests to determine by repeated

Figure 11. Influence of sheet resistance on induced current

runs what effect the enclosure had on voltage drop. One test was made however on isolated bus sections, Figure 1(C), each phase 17 feet 3 inches long. Each phase enclosure was entirely independent electrically of other phases and separated into four 4 feet $3^3/_4$ inch sections electrically insulated from each other. The current in the mains was 4,500 amperes, the phases arranged in flat configuration, and enclosures were 1/8-inch copper. If the current in the mains with no enclosure is taken as 100 per cent, it was found that the enclosure just described permitted a current of 110 per cent to pass with an identical impressed voltage. Short circuiting the insulation between each of the four 4 foot $3^3/_4$ inch long sections permitted 115 per cent current. Removing these short circuits, and short circuiting between phases, so that four 4 foot $3^3/_4$ inch long 3-phase loops were available for circulating current, permitted 113 per cent current. Leaving these shorts and restoring those between 4 foot $3^3/_4$ inch sections so that all three phases were shorted on each other and the entire phase length was shorted on itself, permitted 133 per cent current. The latter approximates the segregated phase bus which is dealt with in most of this paper. This conclusively points out that the reactance of the system is reduced as more and more circulating currents are allowed to flow.

Selection of Enclosure Material Based on Power Loss

It is well known that if the resistance of a duct or sheath around a conductor is plotted against the loss in the duct, that is, I^2R, the curve will originate at 0-0, since $I^2R=0$ when $R=0$. It returns again to 0 at $R=$infinity since $I^2R=0$ when $I=0$ as it must when $R=$infinity. In order to study the shape of this curve a grid made of only five rods as shown in Figure 10 was constructed. Different diameter copper and aluminum rods were used in order to vary R. Because the grid structure of Figure 4 was too difficult to construct each time a rod size was changed, the simplified grid of Figure 10 was used. While the current in the closing rods "X" would be larger with a complete grid, this simplified grid does show the shape and character of the curve equally as well.

The curve shape of Figure 10 conclusively demonstrates the truth of the statement that the curve originates at 0-0 and again returns to 0 at $R=$infinity. It also sharply points up the fact that some type of enclosure (at the top of the curve) is the poorest that could be used and that this condition should be carefully avoided. Currents are also plotted in the figure and it is interesting to note the orderly decrease of I as R is increased. I decreases slowly, however, for large increases of R, showing the reactance of the circuit is large compared to the resistance.

In order to further study this curve characteristic and to link it directly to duct material and thickness, the setup shown in Figure 8 was again used, varying the sheet material and thickness to obtain complete curves. All sheets tested were 2-feet long. This single plate again does not give correct readings for a complete duct but does give a true indication of the character of the curve. Results of these tests are plotted in Figure 11 and detailed in Table I. Since the data are intended to be qualitative and not quantitative, a 1/4-inch section of copper was given a resistance value of 1, a 1/8-inch section a value of 2, and so on. Aluminum and stainless steel were tested for conductivity and given a resistivity rating from this and the sheet thickness. Relative I^2R values were then found by multiplying this value by the current squared and basing values on the 1/4-inch copper. Copper sheets 1/4-inch thick and stainless steel sheets 1/16-inch thick would apparently make ideal materials from which to construct ducts from a standpoint of low temperature rises. One is on the rising characteristic of the curve,

Table I. Rises and Induced Currents in 2'-0"×5'-0" Sheets—Main Conductor Current 5,000 Amperes

the other on the falling. Neither is practical—the 1/4-inch copper because it is too heavy and expensive and the 1/16-inch stainless because it is too thin. Furthermore the circulating current in the stainless is so small that only a small opposition flux would be generated and adjacent steel given less protection. Aluminum sheets of 1/8-inch to 1/4-inch thickness and of good conductivity are the best practical choice. It should be noted that the peak of this curve will move slightly to the right or to the left if phase spacings of the mains are enlarged or reduced.[1] It also should be noted that in all I^2R calculations the d-c value of R is used. Skin effect and proximity effect are neglected since they are of little consequence on these conductors.

This method of testing also allows for the making of qualitative heat runs on the sheets. All sheets were covered with an identical paint so that emissivities were equal and temperature rises could be compared directly. It is interesting to note the small difference in temperature rises between the copper sheets and the 1/8-inch aluminum sheets. In an actual duct this difference would be somewhat accentuated because of the larger closing currents. However, the heat from the main conductor would have to be conducted through these sheets and would be the same in all cases, so the rises in the various ducts would tend to draw together. Note the orderly progression of the various currents and the large differential in temperature rises between the ends of the sheets and the center of the sheets. Readings on the sheet centers were taken along line C-C, Figure 8. This large differential is present even though the sheet is only 2-feet long and the center tends to heat from the end effect by conduction. In long sheets this differential would of course be greater.

It must be kept in mind that in actual ducts, structural members must appear at the ends of sections for rigidity and joining purposes. These will help carry end effect currents, thereby reducing I^2R losses and temperature rises.

It is interesting to compare the power losses in a segregated-phase duct itself and in the main conductor in an approximate manner. Exact comparisons are difficult, if not impossible, because of the problem of measuring induced currents in the housings. From Figure 5, however, we can total the induced current in the rods about one conductor. By comparing the resistance of this group of rods and that of one phase of the duct enclosure shown in Figure 3, a close estimate of the current which would flow in the duct can be found. The I^2R loss can then be calculated for one phase of duct. It is found that this is approximately half the loss in the conductor itself.

Ferrous Sections and Current Loops Outside Enclosure

In Figure 3 note the steel sections laid on top of the duct. These steel members were arranged in a closed loop so that circulating current might flow and of course the steel would heat in itself because of magnetic effects. A maximum rise of 10 degrees centigrade was found at 5,000 amperes which is much lower than the rise would have been had the duct sheet not been interposed between the main conductor and the steel.

In order to study this effect more closely an arrangement as shown in Figure 12 was constructed. When "W" was set equal to 12 1/2 inches the circulating current in the grid could be compared to other readings. When "Z" was set equal to 12 1/2 inches the protection of the duct was demonstrated on outside grids at varying distances. In Figure 12 (B) note that the position of the aluminum sheet made little difference in the current flowing in the grid but its presence reduced the current in rod "X" from 490 amperes to about 85 and the current in rod "Y" from 350 to about 80. See also Figure 10. This is from 17 to 22 per cent of the original current. Since the induced current is proportional to the field strength, we can say the field strength outside the plate was only 17 to 22 per cent of that without the plate. This is due to the opposition currents in the plate. Furthermore if the whole duct were surrounding the conductor, the currents flowing in this plate would be higher, further reducing the outside field and the values of 17 and 22 per cent.

When the distance of the protected grid was changed with reference to the sheet, the current fell rapidly, see Figure 12(C). This is as would be expected. These tests demonstrate conclusively the protecting effect of the sheet metal duct on building steel, conduits, reinforcing rods, and other structural members. Magnetic heating in steel also is dependent on field strength, so that it too is reduced when the net field strength is reduced.

The protection of exterior ferrous members has been studied by others[2] and also can be accomplished by short circuiting loops.

Conclusion

On the basis of this paper and basic electrical theory the following axioms can be formulated for segregated and nonsegregated phase busses:

1. Induced currents in enclosures are proportional to main currents.
2. Decreasing phase spacing of the mains decreases induced currents.
3. Voltages induced are proportional to enclosure length and to the current in the mains.
4. Circulating currents flowing in enclosures reduced the reactances between the main conductors.
5. Circulating currents in enclosures do not increase with the lengthening of the bus after a length of, say, 10 to 20 feet is exceeded.
6. Large end effect currents will flow at the end of each enclosure section and to avoid heating from these currents at every enclosure joint, all sections should be electrically bonded together.
7. Proximity effect in enclosures insulated from each other must be considered since this produces additional heating.
8. On basis of power loss, an enclosure material can be selected which will provide minimum loss consistent with necessary structural strength and economic requirements.
9. Induced currents in enclosures reduce the field strength outside the enclosure to about 10 per cent of that without enclosures.

Discussion

L. H. Ruhlen and **F. D. Morgan** (Commonwealth Services Inc., Jackson, Mich.): This paper is an excellent contribution in a field that has not been too well explored in the past, and there are still unknown quantities where induced currents in bus enclosures are concerned. Installations of this type have been made applying certain assumptions, and corrections applied as required. By applying the information made available in this paper, it will be possible to obtain greater accuracy of design in the future. The method of approach is reasonable, and the results indicate the upward trend of induced current as the bus current is increased. Observations and temperature recordings made of actual installations tend to verify the results obtained in these experiments.

While the paper discusses current ratings only up to 5,000 amperes, it would seem logical to assume that higher current ratings may be considered on the same basis providing the I^2R of the bus structures are kept at a safe value. It appears that this could be done by increasing the cross sectional area of parts of the bus structure where high induced current will be encountered.

There is no discussion of means of reducing hot-spot temperatures where they become excessive. It would appear that a simple way of doing this would be to increase the cross sectional area of the structure where the hot spots occur by welding or otherwise attaching a section of the same kind of metal as the structure.

Maximum safe operating temperatures of the bus enclosures are not discussed, but it is important that the maximum temperature of these structures be such that the allowable bus temperatures will not be exceeded.

Although short circuit stresses on the enclosures have not been discussed, they become important at high short circuit values, and it is sometimes necessary to reinforce the enclosure to prevent distortion under short circuit conditions.

S. C. Killian: Mr. Ruhlen and Mr. Morgan have raised several good points which probably should have been stressed to a greater degree in the paper. A rating of 5,000 amperes has been designated as a top value for this type of bus by our company because of large end effect heating. It is true that heating due to end effect is reduced by increasing the section of the duct carrying these currents. This was verified by comparing the mock duct which was built of sheet only with actual ducts which carried structural members at the ends These structural members did reduce heating because of the reduced total resistance but the gain is not of major consequence. The current still crowds into the very edges of these members and they consequently do not provide as much advantage as might be expected. These hot spot end effect temperatures have to be more or less lived with at the duct ends but it must be remembered that, as mentioned in the paper, the duct usually terminates on a generator, transformer, or switchgear and the rises here will be less than shown because of the large sections in these equipments. Economic facts also must be faced. Considerable expense may be encountered in reducing heating from these end effect currents above 5,000 amperes. It is then possible that it would be preferable to resort to the isolated phase construction of Figure 1(C) which eliminates this type of induced current.

Bus temperatures are limited in all cases to a maximum of 45 degrees centigrade over outside ambient as prescribed by the various standards. Discounting end effect temperatures, all other points on the duct itself will be below the 30-degree centigrade rise prescribed by the standards for locations which may readily be touched by personnel.

The question of short circuits inducing high currents in the enclosure is a good one. These currents will attain considerable magnitude and the forces they will create are provided for by rigidly bracing the entire duct with structural members and forming the side sheets for additional stiffness in the higher capacities.

Centralized Control Board for Steam-Electric Generating Plants

H. L. LOWE
FELLOW AIEE

R. L. HODGKINS
MEMBER AIEE

THE centralization of boiler, turbine, generator, and auxiliary electrical control functions has had considerable attention during the past decade in plans and designs of new steam-electric generating plants. The result accomplished is basically a grouping of the several conventional control boards, formerly placed at scattered locations, into a specific area. The plan of such a typical control room is shown in Figure 1, from which it is seen readily that a considerable area of valuable station space is required and that simplicity of operation has not been wholly attained.

In the design of the new Morgan Creek Plant for the Texas Electric Service Company, a new approach to centralized control for all combustion, steam, and electrical power facilities has been taken. Of greatest importance is the opportunity afforded for one man to have a comprehensive knowledge of the entire plant performance, and for all important operating functions to be under the control of one operator. Another major advantage is that the new design resulted in approximately a 50 per cent decrease in the control-room area and a substantially larger reduction in linear footage of the control panels.

This new and compact centralized control board is of the duplex-type bench-board construction and is shown in Figures 2 and 3 for front and rear areas respectively. Each of the two boiler-turbine-generator sections is 7-feet long. The entire control board, which includes a 4-foot long transmission line control and relay section, is 18-feet long. The structure is 7-feet 6-inches high and 5-feet deep between the vertical panels. The bench section protrudes 1 foot 9 inches beyond the face of the vertical panels. This station consists of 2-unit type boiler-turbine generators. Each boiler is suitable for gas or oil firing, and is rated 220,000 pounds per hour, 925 pounds psi gauge and 905 degrees Fahrenheit. The turbine-generator is rated 20,000 kw, 850 pounds psi gauge, 900 degrees Fahrenheit, 3600 rpm, 13,200 volts. The generator is hydrogen cooled and is equipped with a direct-connected exciter. This plant began operation in June 1950.

Designs are completed, plant construction has begun, and manufacture of the centralized control boards is underway for several other new plants having a combined capacity of more than 700,000 kw.

Centralized control boards now are being furnished for new boiler-turbine-generator units rated 75,000 kw, and it is anticipated that such boards can readily be applied, with only minor modifications to the basic design, to units rated up to 125,000 kw.

Figure 4 shows the operating floor plan of a new 2-unit 132,000-kw plant employing the new type centralized control board. This plant is arranged so that it may be enlarged in the future for the installation of a similar additional centralized control board for the ultimate control of four large units from one central area. Although this may be considered a rather bold step in furthering centralized control to an extent not previously attempted, it is considered logical and reasonable, particularly for the single boiler-turbine type of plant design.

One of the disadvantages of the conventional central control area is the substantial amount of valuable space it requires in the most congested part of the plant. Obviously, to obtain an appreciable reduction in the size of this area, the various boiler, turbine, generator, and auxiliary control panels must be made smaller. In planning and working along these lines, the new and compact centralized control board evolved and has demonstrated its worth in effectively reducing space requirements. In its final design, other economies in plant construction, installation, and operating facilities are being realized.

Compact Design

The compactness of the centralized control board was achieved in various ways. First, careful consideration was given to include only those indications and controls that the central control room operator will require for easy and efficient adjustment of the various boiler, turbine, and generator auxiliaries during normal and emergency operating conditions. Secondly, all front-of-panel instruments, gauges, and control devices were selected to secure minimum size consistent with required readability and accuracy and for ease and convenience of manipulation. Particularly, for the boiler and turbine sections of the board, instruments are of miniature proportions as compared with conventional instruments ordinarily used on boiler-turbine gauge boards. These smaller instruments utilize the principle of retransmission of indications, with low-pressure compressed air as a medium, controlled by transmitters integral with normal full-sized instruments located remotely. This principle of retransmission results in the total elimination of high-pressure piping to the control board, thereby further contributing to compactness of design as well as to installation economies. Finally, the duplex type of construction of the centralized control

Paper 50-223, recommended by the AIEE Power Generation Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 20, 1950; made available for printing August 21, 1950.

H. L. Lowe is with Ebasco Services, Inc., New York, N. Y. and R. L. Hodgkins is with the General Electric Company, Philadelphia, Pa.

Figure 1. Operating floor plan of a recent 88,000-kw steam-electric station showing conventional control room with individual boiler, turbine, and electrical control boards

board facilitates the efficient use of space and provides sufficient area on the rear panels for all recording instruments, watthour meters, relays, and automatic station oscillographs, if required.

Safety

With the elimination of all high-pressure control and instrument piping from the central control board, any possible damage to the equipment or injury to operating personnel from the dangers of live steam, water, oil, gas, or similar hazards is removed. No barriers or compartmentation is required for protection of electrical connection against steam, water or mercury leaks, or spillage. This further contributes to simple and economical control-board construction.

Figure 5 shows the compactness and simplicity of installation of low-pressure piping to a group of gauges.

The control board is of dead-front construction throughout, with no exposed electrical connections on the outside surfaces, which further contributes to safe operation.

Design Advantages

The new centralized control board is flexible in application to various operating requirements and conditions, as space is initially provided for the maximum number of instruments and controls for which need may reasonably be anticipated. For the various control boards already built or now under construction, the only major differences among them are the number of fans per boiler, number of boiler feed pumps, and the differences in fuel usage and in the combustion control systems.

The basic design of the board provides instruments and controls for AIEE and American Society of Mechanical Engineers preferred standard and handbook turbine-generators. It can readily be modified to accommodate central control requirements for the more complicated installations, such as those employing reheat cycles.

Of major importance is the opportunity afforded for saving in operating personnel. Except for the starting of the plant, essential normal operations can be controlled entirely from the control board by one man. In starting up cold, the opening and closing of drains, the starting of miscellaneous motors, and various other local manual operations are required. These are not necessarily simultaneous, but, in general, can be handled by a man who, at other times, attends to routine plant duties.

The compactness and the arrangement of the control board offer the advantage of making it possible for one man to have a comprehensive grasp of the entire plant performance. Meters and gauges are easily read and controls are within convenient reach from the central operating position for one unit. As a result, it is expected that one man can observe instruments and adjust controls for all normal operations in a 2-unit plant. The extent to which this can be done for unusual or emergency conditions will depend upon the capabilities of the operator, and the complexities of the plant and the electrical system to which it is connected.

Another advantage is the reduction in

Figure 2 (left). Front elevation of the new 2-unit centralized control board recently installed at the Morgan Creek Steam-Electric Station of Texas Electric Service Company

Figure 3. Rear elevation of centralized-control board

Figure 4. Operating floor plan of a new 132,000-kw 2-unit steam-electric station showing reduced control room area requirements by using the new 2-unit centralized-control-board design with separate transmission line control unit

size of the room required to house the control equipment. This represents a very sizable saving in structure, lighting, ventilation, and air conditioning costs. Although additional costs for retransmission facilities are involved, the net savings in capital investment by the use of the combined board are substantial.

Functional

A mimic delineation of major units of apparatus such as the boiler and accessories, induced and forced draft fans, turbine, condenser, generator, and shaft exciter, is outlined on the face of the control board. Their arrangement is in a logical manner so that the power production process from fuel to generator output can be readily followed. The various instruments and gauges associated with a specific piece of apparatus are confined within its mimic area as far as practicable. To present to the operator a clear picture of the function he is observing or controlling, the principal runs of piping and electrical circuits are likewise shown in mimic form, and are identified by distinctive colors for the various functions.

Many of the control devices, indicating lamps, and gauges are incorporated directly in the mimic system. Where

Station service transformer controls and instruments. 13. Boiler annunciator (15 indications). 14. Turbine annunciator (21 indications). 15. Generator and transformer annunciator (17 indications)

indicators for similar functions are located close to each other, further identification is facilitated by different colored dials. Safe and unsafe operating ranges are visually shown on pressure-gauge dials by the use of red- and green-colored zones. The green zone represents safe operating ranges, while the red zones, on one or both sides of the green zone, represent abnormal or unsafe operating ranges. To represent valve positions, rectangular signal lamps are located in the mimic piping system, one parallel and one at right angles to the piping, so that both color and position will indicate whether or not a piece of equipment is in use. Green lights at right angles to the piping indicate equipment out of service, while red lights parallel to the piping indicate equipment in use.

Such complete diagrammatic representation should facilitate acquainting new operators with equipment functions. It also should aid in the interpretation of indications and enable fast and accurate manipulation of controls involving both steam and electrical elements in well-coordinated sequential operations. This is of the greatest importance in an emergency.

To indicate the extent of the various control functions and instrumentation provided at each of the two boiler-turbine-generator sections of an installed centralized control board, Figure 6 is shown divided into numbered zones.

Although the design concept of the centralized control board is new, none of the applied components are new or untried. As a result, the development has met with widespread interest and acceptance, particularly for new generating plant designs. Control boards of the new type are now installed, or on order for factory fabrication, for a total of 13 generating units in ten steam-electric stations of eight operating companies. This has made possible a high degree of standardization usually not achieved with a new development in such a relatively short period of time.

Discussion

K. S. Garrett (Philadelphia Electric Company, Philadelphia, Pa.): The modern unit type generating stations of two units or possibly four are particularly well suited for centralized control as described by H. L. Lowe and R. L. Hodgkins. In general, the fundamentals discussed are sound, and it is evident that at Morgan Creek Plant a compact economic safe centralized control room has been constructed.

The use of oil or gas as a fuel, a minimum number of pumps and fans, and a system of combustion control utilizing little board space, appears to have contributed greatly to the high quality of this installation. A change in any of these characteristics might be expected to add considerably to the space required for centralized control. This could be a serious difficulty in connection with small units, but as units become larger, as in the 100-megawatt class and above, it is more likely that sufficient space can be found without adding to the plant dimensions. This was borne out recently when it was necessary to determine the space required to control two pulverized coal fired boilers of 850,000 pounds of steam per hour each and two 125-megawatt turbo generators. Because no detailed plan of control had been decided on, space was allowed for the use of standard size mechanical instruments and the type of combustion control which would require the most panel space. In spite of this, little difficulty was experienced in arranging the panels in an enclosure 36 by 40 feet. This was accomplished in such a manner that very little congestion resulted and well-defined lines of demarkation existed between different control function zones.

The authors state in their conclusion that centralized control has received widespread acceptance, particularly in connection with new generating plant designs. In connection with this acceptance, it is felt that a word of caution should be offered and that each new installation, whether in an established plant or on a new site, should be studied carefully, paying particular attention to the following points: Will the station in its ultimate be of the unit design? Will the full control of the plant be within the reasonable ability of one man to handle? Will the transmission associated with the plant be a very minor part? Can sufficient space be made available at a suitable location for full control of the unit without adding to the building dimensions?

If the answer is not yes to all of these questions, it is possible that centralization of control should be modified or limited.

C. P. West (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Centralized control boards, as described by the authors are a valuable contribution to the control of central station steam and electric generators.

They show a definite trend toward co-ordinating the size and appearance of instruments and gauges. These devices are viewed in the same room by the same people at the same distances. It is obvious that the same sizes, shapes, and dial markings are desirable for both. Circular scales approximately four inches in diameter appear well suited for this application. Larger diameters do not seem justified.

Retransmission by low pressure air has made possible the safe intermingling of boiler room and electrical indications. Further changes to bring more boiler indicating devices into round cases are still desirable.

Manufacturing problems on centralized control boards are somewhat different but, in general, combine the techniques required for gauge board and switchboard construction.

Mimic bus layouts of main electric circuits have been considered helpful in central station operation for years. Extending this reasoning to the complete plant seems entirely logical.

Completely centralized control boards for unit type boiler, turbine, and generator combinations, with their associated auxiliaries, are just going into service. Operating experience is yet to be obtained. Reports on the functioning of these combinations during system or plant disturbances will furnish the final answer as to the part they will ultimately play in station design. A future paper on operating experience would be of great interest. It is hoped that the expected benefits of these new centralized control boards will be fully realized.

H. L. Lowe: A few impressions have been gained in review of various oral and written statements offered by discussers of this paper, which seem to justify further comment by the authors.

Apparently, the opinions of utility engineers vary concerning the extent to which centralized control is feasible. Some would limit the centralization of instrumentation and controls in a single control area to one or possibly two boiler units. Others would group instrumentation and control facilities of one or two boiler-turbine units, but would not install generator controls in the same area. A few consider it feasible to install boiler gauge boards, turbine gauge boards and the generator and electrical auxiliary control boards for one or two boiler-turbine generator units in the same room, however, in general, there has been little or no attempt to arrange the boards so that one operator could observe instruments and manipulate all controls from one location. Control of one or more complete boiler-turbine-generator units from one location and by one operator has been limited, as far as is known to installations employing the type of combined boiler-turbine-generator control board described in this paper. The number authorized, however, now exceeds 25 boards.

The combined boiler-turbine-generator control board does not impose the necessity that full control of a plant or unit be under one man. On the contrary, it provides a means by which all instrumentation can be observed and all or any part of the operation can be controlled by an individual, if this is desired. The extent to which the responsibilities for full operation of one or more boiler-turbine-generating units are imposed in one man is a matter of choice in interpretation of the philosophy of proper plant operation. The important advantage of the combined board is that it permits any degree of centralization of operation, from separate responsibility for one boiler, one turbine, or one generator, to consolidation of the responsibilities for all of these, and, if desired, additional elements of similar units in the same power plant.

Mr. Garrett states that "use of oil or gas as fuel, a minimum number of pumps and fans, and a system of combustion control utilizing little board space, appears to have contributed greatly to the high quality" of

the Morgan Creek installation. Actually, our basic design of this combined board provides sufficient panel space for instrumentation and controls for any or all of the common fuels used in power plants, including oil, gas, and pulverized coal; for various combinations and numbers of forced and induced draft fans; and for various types of modern electric and pneumatic combustion control systems for units up to and including 60/75 megawatt capacity. This is provided on a combined board for one boiler-turbine-generator panel with over-all length of eight feet. Space is provided on the board for up to four pulverizer-feeder groups for coal firing, two induced and two forced draft fan groups, and three condensate-three boiler feed pump groups.

In a recent adaptation of this board for 100/125 megawatt unit installations, using oil, gas, and pulverized bituminous coal for fuel, it was necessary to extend the length of the board by only eight inches to provide sufficient space for layout of instruments and controls for the unit combined board.

Several questions have been raised in connection with employment of centralized control for new generating plant designs, particularly where boiler-turbine-generator unit design is not employed. It is recognized that the maximum advantages of centralized control are realized in the boiler-turbine-generator unit design. However, most of the principles employed in the design of the combined board described in this paper are applicable to any type of plant design—for greater economy, greater compactness, and improved safety of installation. Referring to the unit design, it is anticipated that most future installations will be of this type, so that the advantages in economy and simplicity of operation of this system will be more fully utilized.

Mr. Garrett questions use of centralized control in plants where full control of the plant may not be within the reasonable ability of one man to handle. The combined boiler-turbine-generator control board does not require that only one man be assigned to handle the controls. The combined board merely makes it possible for this to be done if considered desirable. The relative amount of transmission and distribution associated with the plant should have no influence upon whether or not the combined boiler-turbine-generator control board is employed. If transmission and distribution controls are brought to a central location, the facilities for combined supervision are provided, but this does not require that controls be operated by one man. On the other hand, if controls are not brought to a central location, it would be impossible to institute centralized control later without expenditure of a relatively large amount of money—and what seems of even greater importance, the pattern of operation having once been established could not be as readily changed at a later date, because of the psychological aspects.

The combined board is not a development which has established the use of centralized control; it is, instead, a development which has provided the possibilities for realizing more fully the many advantages of this arrangement of controls.

A question has been raised about space requirements for centralized control. The combined board described in this paper requires less space than a boiler gauge board of the conventional type, so that it is likely that sufficient space for a centralized control room housing a combined unit board could be found without necessitating additions to power plant building dimensions.

Mr. West comments on the lack of operating experience with the combined control boards. We concur that it is unfortunate that more experience could not be obtained before it was necessary to employ them in such relatively large numbers. On the other hand, no single element of the board involves any new or untried principle, and nothing done in connection with the layout and arrangement of the boards and the rooms in which they are installed will preclude reverting to decentralized operation, if this is determined to be necessary. The Morgan Creek boards have been in operation approximately six months at this writing and the centralized operation is meeting every expectation.

Practical Experiences with Resonant Grounding in a Large 34.5-Kv System

HAROLD H. BROWN
MEMBER AIEE

ERIC T. B. GROSS
FELLOW AIEE

Synopsis: A large 34.5-kv system was operated ungrounded until early in 1946, at which time resonant grounding was installed, since it promised to be the most effective and most economical method of improving reliability of service. The layout of the system and a description of tests with the ground-fault neutralizer installed are given. Records of operation indicate that the improvements gained by resonant neutral grounding are considerable and fully in line with expectations.

IT IS well known that most faults in transmission and distribution systems are single line-to-ground faults or start as such. Anyone concerned with the problem of improving service on such systems should give serious consideration to the application of resonant neutral grounding, because this method of protection eliminates most ground faults as a source of line outages.

Resonant neutral grounding[1] is effected by grounding the neutral of the power system through a reactor, the inductive reactance of which is within broad margins nearly equal to the magnitude of the capacitive reactance-to-ground of the system.[2] This reactor is called a ground-fault neutralizer or Petersen coil, and is essentially an iron core reactor which is adjustable by means of taps on the winding. Taps at not less than 10 per cent apart are satisfactory, and a current ratio of approximately 1.5-to-1 can be obtained on regular designs without deviating from the required degree of saturation.

Resonant grounding is effective in clearing both transient and sustained single line-to-ground faults. Such faults represent 60 to 85 per cent of the troubles in most systems; they are due to lightning, wind, tree limbs, sleet, birds, small animals, and any other causes which ground one of the phase wires. Since interphase faults develop frequently from arcing grounds, such faults and the consequent outages can be avoided through the arc-extinguishing effect of Petersen coils. Ground faults do not affect the operation of the consumers' equipment, because the line-to-line voltages are not influenced by the occurrence of a ground fault, transient or otherwise, and voltage dips do not occur.

Description of System and Equipment

In 1944, when the greatly increased mileage of the 34.5-kv system of the Wisconsin Michigan Power Company was recognized to be responsible for a relatively large number of faults, various protective measures were investigated. The system was operated ungrounded as a delta system; its mileage of 252 miles of overhead lines could be increased to a total of 353 miles whenever up to 101 miles of a neighboring utility system were connected near Clintonville. Figure 1 shows the 34.5-kv system, which comprises 252 miles. Interconnection at higher voltages with such lines and with lines of neighboring companies takes place at Appleton, Stiles, and at a transformer station between New London and Clintonville. The type of overhead line construction used is shown in Figures 2, 3, and 4. It is the type of tower and pole which has been in general use in systems of this voltage. Figure 4 is of particular interest because of the 50-pair telephone cable installed below the 34.5-kv line. This installation was added in 1948 after resonant neutral grounding had been applied, and no difficulty was experienced by this telephone cable in spite of the fact that many permanent ground faults were on the system for a number of hours each.

In the investigation of means for reducing outages, several possible schemes were considered. One was the installation of static wires, which was found too costly, since ground wires over nearly the entire system would have been necessary. Another was the installation of protector tubes; however, tubes would require solid neutral grounding, and consequently all single line-to-ground faults would produce severe shocks to the system. It should be mentioned here that the system is directly or indirectly connected to twelve paper mills to which power is entirely or partially supplied. Voltage dips or momentary outages are extremely objectionable to such customers because they result in a costly loss of production. Such a voltage dip can interrupt production for at least one hour, and often longer.

Resonant neutral grounding proved to be the least costly solution, and yet it accomplished all the desired features of

service improvements. The system lent itself readily to this grounding method since all lightning arresters are rated for full line-to-line voltage, autotransformers are not in use, and the line sections are well balanced electrostatically; no long single-phase tap-feeders existed.

Ninety per cent of the system consists of flat-type wood poles without ground wires, Figures 2 and 4. Ten per cent are steel tower lines, Figure 3. The smallest size of conductor is number 1/0 stranded copper, which is supported generally on pin-type insulators. Many of the poles also carry 4-kv primary lines and secondary supply circuits. A ground-fault neutralizer with extended time rating, for 80 amperes maximum current and with 15 taps from 80 to 40 amperes, was purchased in 1945 for installation at Appleton. This size provides for a reasonable growth of the network. The cost of resonant neutral grounding of the 252 miles of system was about $51.50 per mile.

Tests

The magnitude of the ground-fault current in the delta system was computed from the mileage and the configuration of phase wires, and the computed value checked fairly well with field tests. Of course, such tests involving the grounding of one of the phase wires should be made through a circuit breaker with fast overcurrent relaying, so that any consequent ground fault will be switched off quickly. However, no consequent faults occurred, an indication that the insulators, bushings, and lightning arresters were in good condition and able to operate at full system voltage to ground. These tests were made with all three phases and the results differed but slightly, indicating that the system was fairly well balanced to ground electrostatically and that no additional transpositions were necessary.

Early in 1946, after the equipment was installed, tuning tests were made on the system during regular operation by measuring the current through the Petersen coil for a number of taps and finding the tap for maximum coil current. This is a simple test that is based on the existence of a small capacitive unbalance-to-ground of the delta system, which unbalance produces the voltage $\boldsymbol{E}_0$ between neutral and ground. Any resonant

Figure 3. Overhead lines 34.5 kv on steel towers

grounded 3-phase system, Figure 5, can be replaced (see Appendix), as far as its zero sequence is concerned, by Figure 6(A), in which R_G, X_G is the ground impedance of the system, that is, the impedance equivalent to the parallel connection of $\boldsymbol{Z}_{AG}$, $\boldsymbol{Z}_{BG}$, and $\boldsymbol{Z}_{CG}$ in Figure 5. If the ground impedance is replaced by a series connection X_G', r, Figure 6(B), a circuit results which will resonate when X_P is equal to X_G'. The current through X_P will be near its maximum for this condition. This method leads to somewhat too large currents as far as compensation for actual ground-fault conditions is concerned, since a properly designed ground-fault neutralizer will saturate at or near phase voltage. However, the maximum voltage $\boldsymbol{E}_N$ across the coil will be only a fraction of phase voltage during this test so that the reactance will be larger than its saturated value. A resonance curve on which I_P is plotted versus the tap position, expressed by the rated current for each tap, does not readily show with which tap, or between which taps, optimum conditions were reached.

Greater accuracy in selecting the proper tap in this test,[8] which is easily made during normal operation of the system, can be reached by drawing the circle diagram of neutral displacement $\boldsymbol{E}_N$. Since $\boldsymbol{E}_0$, Figures 6(A) and (B), is a constant voltage impressed on two impedances in series, one of which, $\boldsymbol{Z}_G(=r-jX_G')$, is constant, while the other, $\boldsymbol{Z}_P$, is linearly variable, the locus of $\boldsymbol{E}_N$ for various settings of $\boldsymbol{Z}_P$ will be the circle shown in Figure 7. Perhaps the simplest method of obtaining the data for such a circle diagram is to measure, for each tap setting on the Petersen coil, the three voltages to ground $\boldsymbol{E}_{AG}$, $\boldsymbol{E}_{BG}$, and $\boldsymbol{E}_{CG}$, together with the line voltages by means of a 3-phase potential transformer with grounded neutral, Figure 6(C).

The results of such tests, made in 1948, are given in Figure 8, where the small circle indicates magnitude and phase of $\boldsymbol{E}_N$ for all possible values of $\boldsymbol{Z}_P$. This system is well balanced and $\boldsymbol{E}_0$ is quite small. However, an increase of unbalance will increase both $\boldsymbol{E}_0$ and the size of the circle, as shown in the same figure. The numbers next to the test points of the larger circle indicate the respective taps 10, 11, and 12. It is easy to see that resonance would exist on a tap between 10 and 11. Because of saturation, tap 11 with the lower rated current should be

Figure 4. Telephone cable under overhead lines 34.5 kv

Figure 5. Resonant grounded system without fault

used, since saturation at full voltage on an actual ground fault reduces X_P and improves tuning. The increased unbalance was produced during these tests by switching off two of the three phases of a short section; this is the simplest way of producing such unbalance for test purposes. It may be mentioned that the same selection of the "best" tap was made from the results of the test which led to the small circle, but the points are so near to each other that the scale to which the figure is drawn does not permit an indication in Figure 8. The average ground-fault current of the system is 0.2 ampere per mile.

Another method of tuning, which is recommended as the best acceptance test and which should include arcing ground tests to show the effectiveness of resonant neutral grounding and the small effect of deviations from resonant tuning by over- and undercompensation, is the grounding of one phase, Figure 9, as staged fault. The equipment used and the instruments needed are indicated in Figure 10 The results are shown in Figure 11, which is self-explanatory. These tests, Figure 11, were made in 1948, in order to find the loss or in-phase component of the residual fault current which is important for the setting of sensitive ground relays.[4] It should be noted that at least two (better three) wattmeter readings are necessary, each with a different line-to-line voltage, in order to resolve the fault current I_F into its in-phase and quadrature components. Practical

Figure 7 (right). Neutral displacement with resonant grounding

experience has shown that ±20 per cent off resonance tuning has practically no effect on the self-extinction of an arcing ground. For this reason the taps on the Petersen coil rarely are changed when line sections are added or switched off. The taps 12 through 15 have never been used.

Performance Experiences

Since resonant neutral grounding was put in service early in 1946 it has never been out of service. It has functioned properly without any repair or maintenance expense. During severe storm periods previous to 1946 it was necessary to dispatch several crews to repair the 34.5-kv transmission lines and substation equipment. Now very little transmission-line trouble is experienced during storms. Since the installation of the ground-fault neutralizer, maintenance crews devote their efforts almost exclusively to rural and distribution circuits. Resonant grounding has made the decided difference.

When a permanent ground fault develops along the 252 miles or more of transmission system, an alarm indicates that a ground fault is on the system and a crew then is dispatched to the trouble and corrective measures are taken.

Resonant grounding has greatly reduced the number and length of outages. For example, there was an average reduction of 40 per cent in the number of outages per year in the 2-year period following this installation. However, the decided gain during the first two years with resonant grounding in service was 81 per cent less in outage time on a mile-hour basis.

Figure 12 shows that the number of operations has continued to reduce each

year since. The reduction in the number of operations of the ground-fault neutralizer in general can be attributed to the gradual elimination of old conductor burns and old insulator damages that prevailed when the system was operated ungrounded. Previous to the ground-fault neutralizer installation, any arcing ground that occurred continued with all its fury until the relays tripped out the line in trouble. Such arcs severely burnt the conductors and the intense heat cracked off skirts from otherwise good insulators. The ground-fault neutralizer prevents the development of high values of arc current, since the arc is wiped out

in a few cycles, at least, if caused by a flashover produced by lightning or other overvoltages. Also, for sustained ground faults the fault current is reduced to relatively small values.

Figure 13 shows in graphical representation an analysis of the causes of ground faults. Note that 46.2 per cent occurred during lightning storms. The operations because of unknown causes are relatively high, since the Petersen coil quenches the transient trouble quickly, so that damage is limited and not readily detected by the operating and maintenance personnel. Figure 13 covers 197 operations over a period of more than 4 years of experience. A recording ammeter, which measures the current in the Petersen coil, and an automatic oscillograph furnish records of the operations.

Figure 14 shows the duration of the 197 operations. Note that over 83.3 per cent are instantaneous. The longest operation was $6^1/_2$ hours. Figure 15 shows the chart of the recording ammeter during this extended fault. Forty-four per cent of the operations occurred in the morning and 56 per cent in the afternoon.

Since resonant grounding was installed, line maintenance crews have noticed that when a 34.5-kv conductor falls on the ground, the usual evidence of severe arcing-to-ground observed previously now produces scarcely any signs of trouble. The ground-fault neutralizer quenched all severe arcing. There have been no unsatisfactory conditions reported for this power system from communication companies because of permanent ground faults or of ground-fault neutralizer operations.

The great improvements brought about by the introduction of resonant neutral grounding are evident from a comparison of outages before and after the installation of the Petersen coil. The number of disconnected mile-hours per year because of faults during the year previous to the installation of the ground-fault neutralizer was 381.87. The mile-hours per year for the first two years after installation was 72.55, or a reduction of 81 per cent.

Conclusions

1. Resonant neutral grounding is a highly effective and most economical method of improving substantially the continuity and reliability of service in subtransmission and distribution systems.

2. Resonant neutral grounding provides protection for transient and sustained ground faults. The number of interphase short circuits is reduced and ground faults are eliminated as a source of voltage dips and other system disturbances.

3. Ground-fault neutralizers require practically no maintenance. Changes of tap settings are rarely necessary since operation is satisfactory on out-of-tune ratios of ±20 per cent and more, whenever lines are switched off or added. Therefore, taps are quite satisfactory if they are 10 per cent or more apart. A current ratio of about 1.5 to 1.0 (currents on maximum and minimum taps) will serve the needs of most systems, and will result in a smaller ground-fault neutralizer with proper saturation characteristics.

4. Reduction of ground-fault currents results in reduced line maintenance since severe damage to conductors and insulators is eliminated. Reduction in circuit-breaker operation consequently minimizes oil and contact maintenance.

5. Residual ground-fault current reductions make possible operation with permanent ground fault for many hours. Maximum duration in this system was more than six hours.

6. A sensitive relaying system to simplify indications of ground-fault locations is desirable.

7. Equipment, including lightning arresters, must be designed for full (line-to-line) insulation to ground.

8. Ground-fault neutralizers designed for extended time rating provide many advantages compared to short time rated equipment.

Appendix. Derivation of Equivalent Circuits

Delta System (Ungrounded System)

Using the notations of Figure 5, eliminating Z_P, since an ungrounded system is considered, and applying Kirchhoff's law leads to the phasor equation

$$I_A+I_B+I_C=0 \tag{1}$$

Loads, as well as capacitances between conductors, are omitted since they do not influence currents and voltages-to-ground directly.[8] If E_A, E_B, E_C denote voltages to ground, equation 1 may be written

$$\frac{E_A}{Z_{AG}}+\frac{E_B}{Z_{BG}}+\frac{E_C}{Z_{CG}}=0 \tag{2}$$

If we call E_{NG} the voltage from neutral to ground, and E_{AN}, E_{BN}, E_{CN} the three phase voltages, the relations

$$E_A=E_{AN}+E_{NG}$$

$$E_B=E_{BN}+E_{NG}$$

$$E_C=E_{CN}+E_{NG} \tag{3}$$

change equation 2 into

$$\frac{E_{AN}}{Z_{AG}}+\frac{E_{BN}}{Z_{BG}}+\frac{E_{CN}}{Z_{CG}}+E_{NG}\left(\frac{1}{Z_A}+\frac{1}{Z_B}+\frac{1}{Z_C}\right)=0 \tag{4}$$

In this phasor equation the following substitution can be made

$$\frac{1}{Z_{AG}}+\frac{1}{Z_{BG}}+\frac{1}{Z_{CG}}=\frac{1}{Z_G} \tag{5}$$

and

$$\frac{E_{AN}}{Z_{AG}}+\frac{E_{BN}}{Z_{BG}}+\frac{E_{CN}}{Z_{CG}}=I_u \tag{6}$$

Both quantities have physical meaning: Z_G is the ground impedance of the system representing the capacitances of the three phase conductors to ground (including leakage). I_u is the unbalanced current of the system, which indicates the degree of electrostatic unbalance.

Since $E_{AN}+E_{BN}+E_{CN}=0$, by definition of the phase voltages, $I_u=0$ if $Z_{AG}=Z_{BG}=Z_{CG}$, because the system is balanced under this special condition. Using the symbols introduced in equations 5 and 6 changes 4 into the form

$$E_{NG}=-I_uZ_G \tag{7A}$$

which equation determines the neutral displacement of the ungrounded system from the two characteristic quantities I_u and Z_G.

This value $(-I_uZ_G)$ is an important quantity which enters into many relations in the following where resonant grounding is considered. Since this voltage is the neutral displacement of the delta system, which may be measured as the voltage between a free neutral (the star point of a large power transformer) and ground, the symbol E_0 will be used, so that equation (7A) takes on the form

$$E_0=-I_uZ_G \tag{7B}$$

Resonant Grounded System without Fault

From Figure 5, Kirchhoff's equation now is

$$I_A+I_B+I_C+I_P=0 \tag{8}$$

or

$$\frac{E_A}{Z_{AG}}+\frac{E_B}{Z_{BG}}+\frac{E_C}{Z_{CG}}+\frac{E_{NG}}{Z_P}=0 \tag{9}$$

Using equations 3, 5, and 6, equation 9 becomes

$$-I_u+\frac{E_{NG}}{Z_G}+\frac{E_{NG}}{Z_P}=0 \tag{10}$$

or if the subscript G in E_{NG} is dropped and equation 7B is used

$$-\frac{E_0}{Z_G}+\frac{E_N}{Z_G}+\frac{E_N}{Z_P}=0 \tag{11}$$

E_N indicates the voltage from neutral to ground in the resonant grounded system, for any degree of tuning. Equation 11 also may be written

$$E_N=\frac{E_0}{Z_G+Z_P}Z_P \tag{12}$$

which equation is represented by the equivalent circuits of Figures 6(A) or 6(B).

Resonant Grounded System with Ground Fault

From Figure 9, Kirchhoff's equation now is

$$\frac{E_A}{Z_{AG}}+\frac{E_B}{Z_{BG}}+\frac{E_C}{Z_{CG}}+\frac{E_{NG}}{Z_P}+\frac{E_A}{R}=0 \tag{13}$$

if R is the resistance of the path of the fault current I_R.

Using equations 3, 5, 6, and 7B, equation 13 becomes

$$E_{NG}\left(\frac{1}{Z_G}+\frac{1}{Z_P}+\frac{1}{R}\right)+\frac{E_{AN}}{R}-\frac{E_0}{Z_G}=0 \tag{14}$$

If symmetrical component analysis is used, the value of R is found to be more accurately

$$R=R_F+\frac{1}{3}(Z_1+Z_2) \tag{15}$$

and the equivalent circuit of Figure 16 results. In this figure $X=A$, B, or C depending upon which of the three phases is grounded. (Z_1+Z_2) is always small with respect to Z_G and can be neglected in all practical applications, E_0 is always small relative to the phase voltage E_{XN}, and may also be neglected under fault conditions. If the ground fault is a solid ground, $R_F=0$, and the residual current in the fault will be, assuming also $Z_1+Z_2=0$, and $E_0=0$

$$I_R=-E_{XN}\frac{Z_G+Z_P}{Z_G\ Z_P} \tag{16}$$

Using equation 12, equation 16 becomes

$$E_N=-\frac{E_0E_{XN}}{I_RZ_G}=E_0\frac{I_G}{I_R} \tag{17}$$

where

E_{XN} : PHASE VOLTAGE OF PHASES X = A, B, OR C
E_0 : NEUTRAL DISPLACEMENT OF DELTA SYSTEM
I_P : CURRENT THROUGH PETERSEN COIL
Z_1 : POSITIVE SEQUENCE EQUIVALENT IMPEDANCE
Z_2 : NEGATIVE SEQUENCE EQUIVALENT IMPEDANCE
Z_0 : GROUND IMPEDANCE OF DELTA SYSTEM
Z_P : IMPEDANCE OF PETERSEN COIL
R_F : RESISTANCE AT POINT OF GROUND FAULT

Figure 16. Equivalent diagram of resonant grounded system

$$I_G = -\frac{E_{XN}}{Z_G} \tag{18}$$

is the ground-fault current of the delta system. Equation 17 may be written

$$\frac{E_N}{E_0} = \frac{I_G}{I_R} \tag{19}$$

which is often referred to as Jonas' equation.[9] It now is possible to predict the diameter of the circles in Figures 7 and 8, since E_0, I_G, and $I_{R(min)}$ are known quantities. E_0 and I_G can be computed and I_R may be approximated from tests in systems of similar voltages. E_N will be largest, if I_R is smallest, that is, for resonant tuning, when $I_{R(min)}$ is the in-phase or loss component of the residual current.

For example, if $\frac{I_{R(min)}}{I_G}$ is 10 per cent (0.1 per unit) and if E_0 is 3 per cent phase voltage E_N becomes

$$\frac{E_N}{E_{XN}} = \frac{E_0}{E_{XN}}\frac{I_G}{I_R} = \frac{3\%}{0.1} = 30 \text{ per cent of phase voltage}$$

This example indicates that the permissible magnitude of electrostatic unbalance (E_0) depends on the magnitude of the loss component of the ground-fault current. At lower voltages, when the losses are larger, larger electrostatic unbalances of the delta system are therefore tolerable. Undesirably large neutral displacements, $E_{N(max)}$, may be prevented: by small values of E_0, by self-detuning through saturation (E_{V2} in Figure 7), by detuned setting,[8] or by increased losses (r_p in Figure 6). Transpositions in substations are nearly always possible and the most economical way of decreasing E_0. Saturation is valuable as protection against neutral displacements under unusual system conditions.

Discussion

Carl Sutter and **W. A. Wolfe** (Kansas Gas and Electric Company, Wichita, Kan.): We have operated with a Petersen coil since February 1947, on a 24-kv system with approximately 69 miles of line. This system was operated for many years with an isolated neutral, followed by one year with solidly grounded neutral prior to installation of the Petersen coil. The number of line trip-outs with the Petersen coil in service runs at about the same rate as with an isolated neutral, but considerably less than during the year with solidly grounded neutral. The extended outage record has been materially improved.

There is some electrostatic unbalance which requires that the coil be operated about two steps off resonance. We have been operating the coil two steps below resonance (at lower reactance) as recommended by the manufacturer. We note in reading the paper by Brown and Gross that where the point of exact resonance was found to be between two tap positions, the higher tap was chosen as the preferred tap. We would appreciate the authors' opinion as to whether the performance of our coil might be improved by operating above resonance rather than below.

We are in agreement with the authors' choice of a coil with extended time rating. We have experienced several instances in which permanent ground faults have been on the line for a considerable time and have been found and cleared without interruption to the circuit.

On the other hand, although line outage time has been greatly reduced following the installation of the Petersen coil, there have been several instances of crossarm fires following indication of permanent-line-to-ground faults. When the coil was installed, it was not believed that the small residual current (calculated to be approximately 1 ampere) flowing into a permanent ground fault would be of sufficient magnitude to cause a pole or crossarm fire. Neither was it thought that the theoretically calculated current of approximately 1.5 amperes resulting from off tune operation would be sufficient to cause a pole to be ignited. However, three cases have occurred in which crossarms were set on fire following a permanent ground fault in which the insulator was cracked or the conductor was lying on the crossarm. If the 1.5 amperes flowing into a ground fault under present operating conditions is capable of producing pole fires, then it is probable that even with a coil operating exactly in tune that the residual current of approximately 1 ampere could be expected to initiate a pole fire under some conditions. Of course it should be remembered that without the Petersen coil, and with the system operating with the neutral isolated, the ground fault current was approximately 8 amperes. Therefore, the likelihood of pole fires has been greatly reduced, but has not been eliminated as was anticipated when the coil was installed.

The authors state that 90 per cent of the system described consists of flat-type wood poles without ground wires. Assuming that this means no ground wire on the poles, we are surprised at the excellent results reported. It would seem that practically all faults with this construction would of necessity be phase-to-phase which would, of course, trip out the circuit. Our line is of similar construction, but there is a ground wire on each pole.

Harold H. Brown (Iowa Electric Light and Power Company, Cedar Rapids, Iowa): Our experience up to now has been with short-time rated coils. Also, we converted from a grounded neutral system instead of from an isolated neutral system. With these differences in application and experience, I cannot, of course, say that I concur exactly with the conclusions expressed in this paper. In general, however, I do agree that our experience largely confirms its conclusions.

We have approximately 1,600 miles of a 34.5-kv system and now have five ground-fault neutralizers in service. The last of these to go in service is a continuous rated coil, but as yet we have not isolated its section of the system from the rest and, therefore, have not had the benefit of the operation of a continuous rated coil. We would be interested in experience and practices in locating and isolating permanent ground faults when they occur as this is the problem which we have to solve before we do isolate this section of our system.

Lawrence M. Robertson (Public Service Company of Colorado, Denver, Colo.): We have one 100-kv Petersen coil in service since 1937 and two 13.8-kv coils since 1944. The 100-kv line is in the Rocky Mountains at high altitudes with a maximum of 13,500 feet and average of 10,000 feet and normally operates with corona loss. The length was originally 225 miles and now 285 miles. The main portion was a pioneer line built in 1909 and operating records indicated a need for improvement. The Petersen coil installation cost was about one-tenth the cost of other schemes such as overhead ground wires.

The 13.8-kv coils are operating on the

Denver system with about 1,500 equivalent miles of line made up of overhead and cable circuits. The coils have continuous ratings.

The authors have presented a very valuable paper on the tests and operation of the 34.5-kv coil. Our experience agrees with theirs, that the tuning is not critical and sections can be disconnected without effect on arc extinction. Our experience has shown that the coils will clear faults where they are of the type which are possible to be cleared. Our experience record is similar to that of the authors.

The continuous rating of the coils is usually justified as the cost is not much more and many faults can remain until they can be cleared later. This is in agreement with the authors.

What sensitive relaying is used by the authors to simplify ground fault locations and do they trip circuit breakers on faults and if so what relaying is used?

C. B. Hinton (General Electric Company, Schenectady, N. Y.): The operating experience on an extensive subtransmission system as described in this paper is an excellent example of the high degree of service reliability which can be obtained through the use of ground-fault neutralizers.

Methods of initial tuning of ground-fault neutralizers have received considerable attention and as a result it is possible to arrive at the correct tap position without conducting line-to-ground fault tests, and without the use of the instruments and potential transformers mentioned in the paper. Thus tuning can be accomplished in a very short time with a minimum number of workers. This method consists simply of tuning for maximum current in the neutralizer and then compensating for the effect of saturation when the data are plotted. It has been used on several systems and the results obtained in this manner have been identical to those obtained from line-to-ground fault tests on the same systems. A complete description of the method is given in the reference listed at the end of this discussion.

The authors' reference to the proper current range of ground-fault neutralizers does not seem to have the same importance as other comments relating more directly to operating experience. The matter of current range must be determined independently for every individual system, most of which require a greater range than 1.5 to 1. The application of ground-fault neutralizers in this country has not followed the same pattern as it has in Europe, where low current ranges are common. In general, our 23- through 69-kv systems were operated for many years with the neutral isolated. When they became too extensive for this type of operation the ground-fault neutralizer offered an effective, inexpensive way of improving service reliability. The ratio of maximum to minimum miles of connected line on such systems is usually greater than 1.5 to 1, thereby requiring neutralizers with correspondingly higher current ranges. In contrast to this, European practice has been to include Petersen coils, as ground-fault neutralizers are called there, as an essential element in the initial system design. As the systems grew larger, neutralizers were added with each new section, thus giving a pattern of several neutralizers with low current range.

American experience on systems equipped with ground-fault neutralizers having current ranges up to 4 to 1 has been entirely satisfactory. It is recognized that if several neutralizers are used on a system the current range need not be as great as 4 to 1. A 2-to-1 range is usually adequate for such a system and also is satisfactory for many systems equipped with only one neutralizer.

REFERENCE

1. TUNING OF GROUND-FAULT NEUTRALIZERS, N. E. Dillow, J. R. Burkhart. *General Electric Review* (Schenectady, N. Y.), December 1949.

Harold H. Brown and **Eric T. B. Gross:** It is indeed gratifying to learn that the experience in other systems has been similar to ours; the interest in this paper shown by many discussers is greatly appreciated and acknowledged with thanks.

Mr. Sutter and Mr. Wolfe point out the improvement in outage record after the change from solid to resonant grounding. This should be of particular interest to many who have not yet considered the merits of resonant grounding. Electrostatic unbalance requires off-tune setting in order to limit neutral displacement voltages during operation without ground faults. Since a properly designed coil will reduce its reactance with increasing voltage because of saturation of its iron core section, the tap with higher reactance will provide the desirable undercompensated "off-tune" setting at normal system condition. However, saturation will reduce this out-of-tune ratio and improve automatically the performance of the Petersen coil during ground faults.

As for pole fires, there have been a few cases in this system where the crossarm was charred and set on fire. However, in some cases a 34.5-kv phase wire has remained in continuous contact with a wooden arm without producing a fire, despite the fact that the residual current on this system is 9 amperes and over. It appears that crossarm fires occurring during single-line-to-ground faults can be prevented or greatly reduced by eliminating cracked or even only hairline cracked insulators. It is advisable to check all insulators regularly in the spring before the lightning season and if possible, once each year, early on a Sunday morning, during tests with one phase after the other solidly grounded and the other phases held for some time at full line to line voltage to ground. These tests have revealed weak spots, helped eliminate the occurrence of subsequent ground faults, and made possible the undisturbed operation of the system during sustained ground faults.

The data given in the paper may be supplemented by the following:

1. None of the cross arms are grounded on the wood poles. Wood V braces are used with the cross arms. None of the hardware is grounded. Wood strain insulators are inserted in the guys from the poles to ground.

2. Most of the steel towers are provided with extra insulation, in many cases with a basic impulse insulation level corresponding to the 69-kv class. It is difficult to discern from operating results any difference between wood poles and steel towers relative to flashovers to ground.

3. The ground-fault neutralizer at Appleton is composed of a 3-phase zig-zag grounding unit and a single-phase Petersen coil in one tank. Had there been available a 34.5-kv neutral of a power transformer, the cost of resonant grounding would have been only about half the amount mentioned in the paper.

Mr. Brown and Mr. Robertson bring up the question of finding the location of a sustained ground fault. The 34.5-kv system is fed from the power plant at Appleton and through step-down transformers at various other points. Therefore, it is possible to locate faults by sectionalizing. For example, if the circuit breaker at Bonduel in the line to Stiles is opened, power will still be supplied from Stiles, but the elimination of this line from the remaining system will help indicate whether or not the fault is still on the Appleton part. In the densely populated areas, trouble is almost always quickly identified and reported. Sensitive ground relays (for indication of the fault location) have not yet been installed, though consideration is given to such equipment which is in use abroad in many similar systems.

A number of engineers expressed approval of the conclusions reached in this paper in discussion and in letters to the authors. Pertinent parts of two of these may be quoted here: "I was pleased to learn that someone in this country is using coils with extended time rating. The large number of automatically switched grounding points involved when using short time rated coils is an expense which might better be invested in extended time rating. It is surprising that only one coil was used on such a large loop with several high-voltage supply points", and "The conclusions reached in this paper are in agreement with our experience with ground fault neutralizers and coincide with my personal opinions."

Mr. Hinton seems to prefer the least accurate method of finding the best setting, a method which is due to Petersen and which was used by him more than 30 years ago during tests with the first installation of a ground fault coil, as Petersen coils[1] are called in most countries abroad. It can hardly be assumed that it is more difficult to read voltmeters than ammeters; however, there is no doubt that an accurate test is generally considered preferable even if it is less simple. We feel that every acceptance test should include arcing grounds. Valuable by-products of such tests are the resolution of the residual current into its fundamental and harmonic components and information about the saturation characteristic of the ground fault neutralizer. Petersen's tuning method referred to by Mr. Hinton does not provide these system data.

The matter of the current range to be selected is certainly dependent upon the individual system, but it is hardly practical to consider only one ground fault neutralizer for a system in which the circuit miles vary by more than the ratio 1 to 1.5. A ratio such as suggested by Mr. Hinton does not mean a wide range coil must be used, but implies separation of the system into two sections which are operated separately. Therefore, the need for two ground-fault neutralizers is indicated, one for each of the two sections for protection which will be independent of switching conditions at all times. The ground-fault neutralizer used in this system has 15 taps. Neither taps 13 through 15 nor the taps near the upper cur-

rent region have ever been used. The minimum current to be considered in this system is 46 amperes, the maximum current 65 amperes, that is, a range of 1 to 1.4. The advantages of a small range are mentioned in the paper. As for the 1 to 4 ratio, from a paper by E. Herzog[2] may be quoted: "Improvements suggested by experience." . . . . . "The higher than normal range (1 to 4) of coil reactance has never been used, and large decreases in system capacity are unusual. It would have been a better design to put existing needs near the upper limit and use most of a smaller range for future expansion."

A recent survey[3] concerning the application of resonant grounding in the United States has indicated that taps are never being changed in as many as 27 per cent of all the systems so grounded in this country. It is evident that these systems do not need ground-fault neutralizers with a 1-to-2 range; much less than the 1-to-1.5 range suggested in this paper would do excellently. Future designs should consider this experience gained by many operators.

The same survey[4] also shows that other data referred to by Mr. Hinton are not based on facts. For example, of all systems in this country above 22-kv now resonant grounded, only 33 per cent were previously ungrounded, 52 per cent were changed from some other grounding method (35 per cent from solid grounding) to resonant grounding, and 15 per cent were new systems designed to be resonant grounded. We happen to know from first-hand experience that the European practice has been exactly what Mr. Hinton describes as the practice in this country. In general, systems operating at voltages below 66 kv were ungrounded until they became so extensive that resonant grounding (and hardly any other grounding method) was introduced to provide reliability of service. The European systems in this voltage range grew very much like those in this country. The reasons discussed above and the problem of saturation[1] were responsible for the selection of current ranges of less than 1 to 2 in all but a few exceptional cases.[1] The name Petersen coil has been in common use in this country with American operating engineers. It is even used in the titles of nine papers dealing with operating experience[4] published in this country, whereas three papers refer in their titles to resonant grounding, one paper to Bauch transformer and only two to ground-fault neutralizer.

Transformer Noise and Its Confinement

CORBETT McLEAN
MEMBER AIEE

RAPID INCREASES in population and load density necessitating the installation of larger transformers, the scarcity of suitable substation property, the noise consciousness of the general public, and the practice of working the new oriented or cold-rolled core steel to a high flux density, have recreated a major problem which must be considered and solved by all electrical utilities operating in well-developed residential areas. Low-frequency transformer hum is apparently a noise to which the average resident has not been accustomed. It differs from the routine traffic disturbances contributing to the general din which all modern city dwellers casually accept but which would have driven our forefathers from the confines of the city. The awareness of the utilities to the problem of transformer noise is demonstrated by the numerous papers presented at engineering and operating meetings and the experiments in wall and building construction.

This paper concerns the noise problems encountered after the energization of a newly installed unit substation in a residential area. It describes the attempts made, under pressure to relieve adjacent substations of severe overloading, to secure immediate temporary reduction of noise level by drapes and noise cancellation devices, to readily accumulate sufficient data from other utilities and from technical papers to permit an engineering approach to the problem, and to make tests on various building materials locally available for insurance of an adequate permanent reduction in noise level at reasonable cost. A 4-walled enclosure consisting of sand-filled hollow pumice block with partial tile roof was finally designed and built with satisfactory results.

Conclusions and recommendations include: (1) insistence to manufacturers for more consideration in design of noise free transformers; (2) procurement of sufficient substation property; (3) comparison of costs between excessive premium for reduction of innate transformer noise level below National Electrical Manufacturers Association (NEMA) Standards and sound insulating enclosures; (4) selection of material for enclosures plus desirability for energization of transformer before completion of sound attenuating device; and (5) improvement in appearance of the substation.

Installation of Substation and Complaints

In the fall of 1949 the Pacific Power and Light Company completed installation of a 15,000/25,000-kva 110/66–11-kv unit type substation with four feeder positions in a residential district in the southeast section of Portland, Oreg. Factors entering into the selection of the site included: (1) close proximity to the load center; (2) size of ground area; (3) availability of property; (4) zoning code restrictions; and (5) ease of entrance of transmission tap line and egress of distribution feeders.

A site measuring approximately 70 by 95 feet was the largest area which could be secured to satisfy requirements. This property was located on an arterial thoroughfare flanked by a medium class residential district. Owing to the somewhat limited size of the property acquired and the advisability of leaving space for future duplexing of the station, the transformer section of the initial unit was placed at the east end of the property which was relatively close to an adjacent frame dwelling, Figure 1.

When the unit substation was energized for service, residents in the area adjoining the substation vigorously complained of disturbing noise. The distribution of dwellings in this vicinity and the location of residents voicing these strenuous complaints are shown in Figure 2. Reflections from buildings created a crazy-quilt pattern of noise intensity.

An investigation which included sound level tests based upon NEMA Standards was made. Briefly these tests consisted of averaging the readings taken at a number of points around the transformer at specified heights and at a distance of one foot from the major sound producing surfaces. Since the switchgear cubicles were in place, all NEMA recommendations for tests could not be fully complied with. The performance standards prescribe that for a 15,000-kva 115-kv oil-immersed self-cooled (class *OA*) transformer the average sound level shall not exceed 75 decibels without fans and 79 decibels with fans when energized at normal voltage and frequency with no-load. Tests indicated average sound levels of 71 decibels and 73.5 decibels respectively on the *A* or 40-decibel frequency weighted scale with a maximum of 81.5 decibels without fans. All readings subsequently used in this paper are without operation of fans.

To further aggravate conditions, the daytime average ambient noise level was approximately 40 decibels; but because of almost continuous heavy daytime traffic on Division Street the intermittent sound level rose at times to 100 decibels. This condition made the transformer noise at night seem more intense. To maintain good public relations and avoid statute violations of a zoning ordinance, a means of reducing the noise level of the substation became imperative.

Preliminary Experiments

To suitably attack the problem and provide temporary relief it was necessary to explore the proportion of earthborne

Paper 50-225, recommended by the AIEE Transformers Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 17, 1950; made available for printing August 21, 1950.

CORBETT McLEAN is with the Pacific Power and Light Company, Portland, Oreg.

and airborne noise and to determine if the predominating frequency was that of magnetostriction, 120 cycles per second. Physically very little vibration could be felt on the substation pad and none could be noticed in the surrounding earth.

By the use of available equipment including contact and crystal microphones, Ballantine vacuum tube voltmeter, and cathode-ray oscillograph, it appeared that the resonant frequency of the concrete pad was 600 cycles and that of the transformer shell was 720 cycles. The contact microphone was utilized to measure this vibration. The contribution through the surrounding earth was apparently negligible. With a crystal microphone accurate from 50 to 10,000 cycles per second it appeared that the major airborne frequency was 240 cycles. Later information included in this paper showed that the frequency varied with the test location.

A quantity of burlap was purchased and a double layer approximately 20 feet by 20 feet was suspended between the transformer and the nearest residence. Even with many folds in this form of drape and with the burlap later saturated with water, no improvement could be observed. A better understanding of the distinction between sound absorption and sound insulation would have eliminated this test.

Noise cancellation was then attempted as another temporary expedient. A high-fidelity crystal microphone was used in conjunction with a very linear audio amplifier to drive two 12-inch cone-type speakers 180 degrees out-of-phase with the noise source and pointed in the direction of the desired noise reduction. The speakers were positioned about the transformer without accomplishing any successful improvement. The sound wave lengths of the various frequency components later determined to be present, ranged from approximately 10 inches to 9 feet.

Because the microphone could not be located at the same spot as the speakers on account of feedback and because of the multiplicity of sound generating sources on the transformer, the cancellation of noise from one source was offset by the reinforcement of noise from another source. However, additional thought is being given to this idea for possible future installations requiring temporary immediate relief. Perhaps some solution may be found for effective unidirectional cancellation for local areas perpendicular to a major transformer surface.

Compilation of Available Information

An accumulation of data through correspondence, review of technical papers, and inspection of installations of other utilities confronted with similar problems, resulted in a collection of information concerning intercepting walls on one or more sides of the transformers, resilient pads under transformer bases, inner liners in compartments, heavy plantings of shrubbery, enclosures, and complete masonry buildings. All emphasized the severity of the problem and the impossibility of an exact analysis with specific improvement per dollar expended. In addition to the uncertainties of proper evaluation of noise measurements, the equation of ear response versus human reaction was most disturbing.

Figure 3. Equipment and samples employed in making sound insulation tests

The following excerpts adduced from a recent technical paper by C. E. Baugh[1] were extremely pertinent:

1. Units of the same design show a wide variation—as high as 12.5 decibels—in sound level.

2. Units with cold-rolled steel cores have an average sound level about 7.5 decibels higher than that of earlier units built to the same specifications.

3. The housing of unit substations is contrary to the philosophy under which this type of apparatus was developed.

The study of information led to the conviction that the only solution for a substation of such a high noise level was the construction of a suitable wall or barrier around the unit that would effect the reduction of the noise level at the locations of the complainants without interference with necessary ventilation and operation.

Some thought was given to the use of sound metal panels in place of a masonry enclosure. The panels, as manufactured, were constructed of a heavy steel frame faced with perforated metal, and where exposed to the weather, the outside sheet was of solid metal. Separators were placed in between the steel sheets and a

Figure 6 (right). Enclosure before roof section was added

high-grade spun mineral felt packed within. This resulted in a meritorious product having high absorption coefficients at the lower as well as the higher frequencies. The cost of a complete enclosure of the substation with sound metal panels was estimated to be considerably more than masonry construction. No data were available on the efficiency of these panels as sound insulation.

It is important at this point to note that there are two distinct problems encountered when dealing with sound. These are sound absorption and sound insulation. Sound absorption deals with the dissipation of sound incident upon a surface. In other words, a material having a high absorption coefficient will permit minimum reflection and reduce reverberation. Sound insulation applies to the reduction of sound intensity level when transmitted through a structural wall. It is the problem of sound insulation with which one is confronted in attempting to reduce transformer noise by the erection of walled enclosures. Practically all acoustical information on hand dealt with sound absorption.

Lacking definite information on the sound insulating qualities of the various acoustical materials, a series of tests were conducted on those thought to be most suitable for exterior application. Experiments were made on various acoustical wood fiber, cork, Fiberglas, and asbestos boards but it was soon evident that these lighter materials were not efficient sound insulators. The attenuation of noise passing through these substances was insignificant. No suitable practical method was evolved to satisfactorily check published data on the sound absorption coefficients of these materials. Differences in reflection (and absorption) between panels of fiber board, pressed shavings, plywood, and polished marble could not be detected with existing equipment.

These tests and previously published information on the efficiency of sound insulating walled enclosures, indicated that materials having large masses were required for efficient noise attenuation. This explains why tests by this company and other utilities using burlap or canvas walls as sound insulators produced negligible improvement. Particular attention was therefore given to the various types of masonry blocks available in the area.

The test procedure consisted of providing a directional noise source, a wall of the material under test, and a sound measuring device. As illustrated in Figure 3, the noise source was provided by enclosing a speaker in a heavy plywood box open on one side and lined on all inner surfaces with acoustical board. The speaker was driven by an audio signal generator and a very linear audio amplifier which permitted control of both the sound intensity and frequency. The material under test formed the remaining wall. A General Radio Company sound level meter was used to measure the sound intensity before and after the wall was in place—the difference between the two readings being an indication of the sound insulating efficiency of the wall material under test.

Figure 4 illustrates the sound reduction obtained for frequencies from 120 cycles per second to 10,000 cycles per second by the use of walls built of concrete, pumice, and concrete sawdust blocks with and without sand filling. A very noticeable increase in sound insulation at the lower frequencies was obtained in each case by filling the hollow blocks with dry sand, an average of 12 decibels at 120 cycles per second for the three types under discussion. Possibly because pumice blocks were good sound absorbers as well as good sound insulators, the sand-filled pumice block construction appeared the best and was chosen for the construction of the substation enclosure. In contrast to these findings, one of the manufacturers repeatedly expressed an opinion that even though the sand would add to the mass of the walls it was doubtful if it would have any beneficial effect external to the enclosure. Although blocks were immersed in water to measure its absorption, no tests were made to determine the characteristics of wet sand. However, sound

Figure 8. Rear of completed enclosure showing tile roof, service entrance, and closed vents

Figure 9. Interior of enclosure showing I-beam support for baffle wall

dampening qualities of sand were believed to be better when dry and provision was later made to keep the sand in this dry condition.

Following considerable study of sound absorbent materials, 2-inch thick pressed Fiberglas panels of the type used for roof insulation were selected as an inner liner

Figure 10. Interior baffle wall and I-beam support

to provide the most suitable means of additional sound absorption if such were found necessary upon completion of the building. By using pumice-block construction these panels could be nailed directly to the inside of the wall.

Design of Structure to Confine Noise

With hollow pumice blocks filled with sand showing superior qualities as a wall material, the task of designing an enclosure that would produce the expected results at a minimum of cost and with an appearance that would be in keeping with the buildings surrounding the substation location was undertaken.

In addition to strenuous objections of residents whose locations are illustrated in Figure 2, there were many complaints from customers at random locations about the substation. The noise pattern observed led to the conclusion that a 2-sided enclosure would probably cause sufficient reflections to create hot spots of even higher than original intensity on the unprotected sides. The exposure of the substation to the public in the adjacent main traffic artery also was a potent argument for an acceptable appearance. Although a complete roof did not seem practical on account of the high-voltage leads, a partial roof seemed necessary to eliminate line of sight noise transmission and to reduce spill-over.

The enclosure finally adopted consisted of four closed walls 24-feet wide, 46-feet 8-inches long, and 16-feet 6-inches high built of pumice block masonry, using 8 by 8 by 16-inch units erected on a reinforced concrete footing poured independent of all other station foundations, Figures 5 and 6. The height including partial roof was 21 feet 8 inches.

The cavities in the individual blocks were filled with sand after every six or eight courses of block were placed. Clean dry sand was used, well rodded to insure complete filling. The 4-inch thick glass block panels, which were added for decorative purposes only, measured 6 by 8 feet and were backed with 4 by 8 by 16-inch pumice block also sand-filled to provide full wall thickness at all points. Corner columns were built up of standard block units, concrete filled to provide additional strength and to comply with the city building code.

Pumice sand was used in the mortar to provide a material having nearly the same expansion coefficient as the blocks themselves. Placed longitudinally in the mortar joint between every third course of blocks were steel reinforcing rods which served to reinforce the wall structurally

Figure 11. Interior of structure

Note small wall of uncemented pumice blocks originally installed to reduce sound transmission through ventilating openings

and provide a method of stopping expansion cracks which might develop. The walls were capped with a partial roof consisting of a poured reinforced concrete slab covered with clay roofing tile, Figures 7 and 8. The contractor was given the option of constructing the roof by use of the conventional wood forms or by the "Hy Rib" method which employed metal lath and cement plaster. He elected to use the wood-form method.

The internal baffle wall mounted on an I-beam shown in Figure 9 and extending from a height of approximately 9 feet

Figure 12. Progressive sound level tests of pumice block enclosure during construction

above ground to the top of the roof had a 3-fold purpose. First, it provided a wall close to the transformer for acoustical effect. Second, it furnished support in the long span of the roof slab. And third, it provided a division wall which would help the chimney action in the enclosure by directing the warm air around the transformer to a direct path upward, see Figure 10. The vertical I-beam used to strengthen the barrier can be easily identified.

Screened ventilation openings 16 by 16 inches were provided on three sides at the bottom of the walls. These were originally shielded from direct noise transmission to the outside by a low baffle wall approximately 18 inches from the inside of the main wall and approximately 36

Figure 13. Comparative sound level tests showing effectiveness of enclosure

inches high, Figure 11. In an effort to further attenuate the noise, the openings were closed with 4-inch sand-filled pumice blocks on the interior side. The chimney action produced by the inner baffle wall apparently provided adequate ventilation.

Provision for internal lining of the enclosure roof with the Fiberglas insulation was made by placing wooden nailing blocks in the concrete as poured, Figure 7. Furring strips could be nailed directly to the pumice walls as supports for the insulating material. To date, noise reduction seems to be sufficiently effective to alleviate the necessity for this inner lining.

In order that the transformer might be removed in event of an emergency, a panel of block was laid up in the front wall with vertical joints between pilasters. A concrete beam spanning between these pilasters supported the roof over this distance and sufficient vertical clearance was provided to permit removal of the transformer after removal of the bushings. Tap changer compartment, feeder cubicles, and other portions too large for passage through the 4 by 7-foot metal door could be removed by a crane through the opening in the roof.

Consideration was given to the installation of a large service door for removal of the transformer. One of the midwestern utilities constructed such a door or panel from 2-inch glass fiber bats completely enclosed in 20-gauge sheet steel. Although this panel proved to be almost as effective as a masonry wall the cost of a similar panel was prohibitive when the anticipated infrequency of its use was considered. Estimates showed that the masonry section could be removed and replaced three times before the cost of the metal panel was exceeded.

Before, during, and after completion of the enclosure, tests of sound level intensities were made at prearranged locations or stations to determine, by comparison, the effect as various additions to the enclosure were completed. The completion of the entire enclosure was necessary before appreciable noise reduction was achieved. This reduction through the wall averaged 23 decibels on the *B* or 70-decibel scale.

Attenuation at the property line on all four sides of the substation varied from 15 to 24 decibels with an average of 18.5 decibels. As expected, the intensity level increased inside the enclosure because of reflections. Results of these tests are shown graphically by Figure 12 for specific locations on all four sides of substation (described in Table I), selected for comparative purposes. Figure 13 shows the position of all test stations with most of the comparative readings taken before and after the construction of the wall. Readings were taken throughout on all three scales of the sound level meter but because of the high intensity levels encountered the *B* or 70-decibel scale was used for the most practical comparison. All readings were taken with the microphone about 12 inches above ground contour which varied approximately 3 feet. Initial and subsequent checks indicated practically no difference in readings beyond a few feet from the transformer at different elevations. Some of the erratic readings during construction are attributable to the presence of piles of pumice blocks, sand, and other temporary foreign material.

Table I. Explanation of Data Shown on Figure 12*

Test	Date	Time	Notes
1	10/31/49	1 to 4 p.m.	Before construction was started on sound barrier. See Figure 1
2	2/13/50	1:30 to 3 p.m.	Average height of pumice block wall—5 feet above ground level
3	2/16/50	9 to 11:30 a.m.	Average height of pumice block wall—11 feet
4	2/25/50	1 to 4 p.m.	Average height of wall—15 feet
5	2/27/50	3:30 to 4:30 p.m.	Wall completed to full height of 16 feet 6 inches and filled with sand. Door and all ventilators open. See Figure 6
6	4/3/50	1:30 to 4 p.m.	Roof completed. Door in place. All ventilators open. Complete except for inner baffle wall in front of ventilator openings
7	4/10/50	1:30 to 4 p.m.	Sound barrier completed. Inner baffle wall in front of ventilating openings, in place. See Figures 11 and 15

Figure 14 (left). Front of pumice block enclosure after completion

Figure 15 (right). Substation transformer and adjacent dwelling after completion of enclosure

that the noise ranged from 120 to 1,560 cycles per second and that the predominate frequencies were either 120, 240, or 360 cycles per second depending upon test location and the progress of the enclosure construction. The transformer auxiliary equipment provided local sound sources of varying frequency and intensity.

It did not appear that effects of variation in ambient noise level were less for any specific frequencies. There seemed to be as much variation in the frequency analyzer readings at any given frequency due to ambients as there was for the total of all frequencies emanating from the transformer.

The completed structure before planting of shrubbery is shown in Figures 14 and 15. A sage green color included in the waterproofing for the outside surface made a pleasing combination with the red tile roof. A sprinkling system later was installed and the lawn planted. The shrubbery, some of which is fairly large, will be transplanted in early fall.

During the assembly of materials and approximately two weeks before start of the enclosure construction, the substation was energized and left in this condition until it was necessary to remove the voltage on the high-tension leads because of progress on the walls.

Conclusions

From experience gained in the attempt to reduce the transformer noise level, the following suggestions are offered when the installation must be in a residential area:

1. Continue to press the manufacturers for more uniform assembly with noise level an important feature in the design. The extreme variation in sound levels of identical unit substations included under the same purchase order is a strong factor in this argument.

2. If possible, procure enough property so that the transformers can be placed at least 100 feet from the nearest dwelling.

3. Compare the additional cost of a more quiet transformer with the construction of a sound confining enclosure. There exists a 25 per cent increase in price for designing transformers at 10 decibels below NEMA levels. A 20-decibel decrease in noise level might therefore increase the transformer cost by 50 per cent. Several enclosures could be built for this high premium. The almost universal consensus of those contacted appeared to be that this cost is unwarranted and that the best procedure is to energize the substation and then apply remedial measures if required.

4. If an enclosure is economically advisable, select for its construction the available material that provides the best sound insulation and at the same time the greatest sound absorption. Energize the transformer two weeks before construction is started and as much as possible during construction in an effort to accustom the neighborhood to the noise and obtain a psychological advantage as well as actual noise reduction.

5. Improve the appearance of the substation and property as much as economically justifiable by landscaping, lighting, and painting of structures.

Discussion

T. D. Gordy (General Electric Company, Pittsfield, Mass.): Mr. McLean has presented an excellent paper covering the reduction of transformer noise level at an installation. The author's complete description of the procedure should be very worthwhile to other operators confronted with similar problems.

The difference between sound absorption and sound insulation is one that often is not fully appreciated. The author's comments on this difference are most timely; realization of what is the difference between absorption and insulation will eliminate many failing attempts of various noise reduction methods for particular cases. This applies to noise suppression within the transformer as well as to enclosures described by Mr. McLean.

The first conclusion drawn in the paper is that manufacturers should be pressed for more uniform assembly, with noise level an important feature in the design. Manufacturers are more desirous of uniform assembly than are the operators; variations in assembly and construction require large design tolerances, and these tolerances are costly in design time and material utilization. In its simplest form, transformer noise is a very complex problem for the manufacturer,[1,2] and variations introduced in processing and assembling transformers lead to more complexity. That manufacturers consider noise level an important feature in design is demonstrated by technical papers of the past year.[1,2,3]

Related to the third and fourth conclusions of the paper is an important contribution that must come from the operator—that of determining what noise level will be satisfactory for the installation. Economic appraisals of noise reduction methods cannot be made until an acceptable noise level has been determined for the installation. Some data are available on acceptable noise levels,[4,5,6] but more investigations are needed. It is hoped that findings of such investigations will be reported as completely as the one presented by Mr. McLean.

T. R. Specht (Westinghouse Electric Corporation, Sharon, Pa.): This is a timely paper that gives quite well the problems involved in installing a large transformer in a residential district. The problem of transformer noise is becoming more serious as the size of residential loads increase and consequently the size of the transformers increase. Even a transformer as small as 1,000 kva may cause complaints if it is in a quiet location and is installed near a residence.

The tests given in this paper bring out a point that should be emphasized. Although the sound attenuation near the wall due to the wall is relatively large, the paper gives 23 decibels, at greater distances the attenuation decreases. The average attenuation due to the wall, from the tests for distances over 40 feet, is 9 decibels. A wall gives more attenuation near to the wall than farther from the wall. This represents about the average results that can be expected with a wall.

In the paper, they stated that they filled the pumice blocks with sand as their tests indicated that the sand increased the attenuation at the lower frequency. Pumice block must be quite porous, for one reference[1] gives an attenuation of 8 decibels at 128 cycles for 4-inch thick pumice block and with the same block with one side plastered the attenuation was 31 decibels. The paper gives an attenuation of 17 decibels for a plain 8-inch pumice block, and 36 decibels for a sand filled block. The amount of sound insulation which will be useful in the wall will depend on the attenuation secured with a perfect wall at the desired point. For the case in this paper, the transformer was practically on the property line, and the measured attenuation was about 23 decibels. The wall attenuation should be appreciably higher than this figure so it would be justified in this case to use a wall with 36-decibel attenuation. If the point at which it is desired to reduce the sound level is 40 feet out from the transformer, the attenuation secured was only 9 decibels. At this distance considerable sound bends over the wall back to the ground, and the wall could have less than 36-decibel attenuation and not increase the sound level at the point of measurement to any extent.

The paper quotes from a paper by C. E. Baugh that units with cold rolled steel cores have an average sound level about $7^1/_2$ decibels higher than that of earlier units built to the same specifications. It is presumed that this means the same electrical specifications which means smaller size and weight. It may be true the sound levels are higher, but it also is true that if the same transformer has cold rolled steel substituted for older hot rolled steel, it will be quieter. The tendency has been, though, to use the new cold rolled steels at higher inductions than the old steels because the losses are much lower for the new steels. This makes a less expensive transformer for the customer and for the majority of locations is quite acceptable.

The past practice of a certain percentage price increase for a certain decibel reduction for all sizes of transformers has not been in agreement with the actual costs. A recent paper by A. J. Maslin[2] has shown that a small transformer will cost a much higher percentage for the same decibel reduction from the NEMA standard[3] than a large transformer. From the curves in Mr. Maslin's paper, a 25,000-kva transformer designed to a NEMA level of 76 decibels would weigh 35 per cent more if the sound level were to be 67 decibels instead. The cost increase would not be as much, but would probably be around 20 per cent. Some manufacturers now are pricing more in line with actual costs, which for the smaller transformers, means the premium for quieter transformers is quite high.

In general, the procedures outlined in the paper for installations in residential areas are to be recommended. For the very large transformers, though, it may be necessary to have a special quiet transformer in addition to the use of a sound barrier around the transformer.

Simplified Subscriber Toll Dialing for Low-Rate Low-Density Toll Circuits Between Community Dial Offices

ERIC BROOKE
MEMBER AIEE

J. M. BLACKHALL
MEMBER AIEE

W. H. BLASHFIELD
ASSOCIATE AIEE

WITH the installation of more and more dial telephones and the replacement of operators with automatic switching equipment, increasingly difficult problems appear as the simpler installations are completed. One of the problems is the handling of short-haul toll calls between dial exchanges. If it is necessary to retain an operator to handle only toll calls, the small exchange dial conversion cannot be justified, as the same operator also can handle the local switching.

This situation has been met with various partial solutions involving special trunking arrangements and special circuits to permit operators at distant points to complete toll calls. With increasing costs of operating and of line construction, this procedure has become awkward and expensive, so that the need for some different solution has become apparent.

Some of the present accepted methods of establishing toll calls between automatic exchanges are:

1. With dial-back operation a call is established from one automatic exchange to an operator office. The operator then dials back over the trunk on which the call was received, completing the connection to the second automatic exchange. This is illustrated by Figure 1(A). This procedure is expensive in toll line mileage, as it holds a circuit to the operator office in addition to the one between dial exchanges. A modification which has been used to reduce circuit usage is to permit the operator to release the trunk to her office, leaving the connection established only between the two dial exchanges. With the operator released, it is not possible to time the call; subscribers recognizing this condition tend to carry on unnecessarily long conversations from which no corresponding revenue is derived. As a correction, automatic time disconnect has been provided in some instances, interrupting the call after a predetermined time. Time disconnect, however, often meets with adverse customer reaction.

2. Complete the connection through a third office at which an operator is available. This method is also wasteful of toll line mileage, as the route through the manual office may be considerably longer than the direct route between the two dial exchanges. Figure 1(B) illustrates such a situation. Furthermore, the services of an operator on short-haul calls may cost more than the revenue derived from the calls.

3. A third practice is to abandon the toll charge between automatic exchanges, permitting subscribers to dial nearby exchanges on what is known as a "free-service" basis. It must be realized, however, that the term "free-service" is misleading, for the cost of providing this service must be spread among all the subscribers at both exchanges, with the result that subscribers who make little use of the so-called "free" service are helping to pay for those who do use it. Furthermore, offering free-service increases the traffic so that the operating company may be faced with the necessity of providing more circuits between exchanges. It usually is not easy to obtain increased exchange rates to pay for the increased investment.

Development

The period from 1930 to 1940 saw the start of widespread conversion of small exchanges to dial operation. During the latter part of this period, the need for some better solution to the short-haul toll problem became obvious. The war years, however, interfered with normal development, so that it is only since 1945 that our company has been giving intensive thought to a different solution. Some form of automatic ticketing appeared desirable, permitting the toll call to be completed in a manner similar to a local automatic connection. In other words, a subscriber in one exchange would be able to dial numbers in other exchanges, with trunk equipment automatically producing a record of calling and called numbers and duration of conversation.

It is realized that an automatic ticketing system will not completely handle all toll requirements, as person-to-person, collect, and paystation calls still must be supervised manually. With short-haul traffic, however, the percentage of person-to-person and collect calls is small. It is probable that the introduction of automatic ticketing will tend to reduce the types of call that cannot be handled over it. The appeal of easily dialing a number in a distant office is expected to encourage the placing of station-to-station calls in preference to person-to-person calls via an operator, particularly in the low-rate situations for which this system is intended.

Simplicity and economy of equipment are of utmost importance in a ticketing system for low-rate low-volume traffic. In the first place, the revenue to be derived from this class of traffic will not support a large investment or skilled maintenance on highly complex apparatus. Secondly, the expansion of large urban areas to the surrounding countryside and the tendency of some state commissions to advocate county-wide service on a flat rate basis is causing the free-service situation to become more and more prevalent; therefore the possibility of obsolescence limits the prudent investment in ticketing equipment. Design of the apparatus also should contemplate more or less ready removal from one location to another, to make maximum usage of the investment.

Low cost has necessitated thinking

Paper 50-227, recommended by the AIEE Communication Switching Systems Committee and approved by the AIEE Technical Program Committee, for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 24, 1950; made available for printing August 22, 1950.

ERIC BROOKE, J. M. BLACKHALL, and W. H. BLASHFIELD are all with the North Electric Manufacturing Company, Galion, Ohio.

Figure 1. Methods of providing for toll connections between dial offices

(A) Dial-back method (B) Switching through third offices

along different lines from other automatic ticketing systems which have been designed for large urban areas. Salient points of these other systems are:

1. Automatic identification of the calling number.
2. A recorder which registers information in printed form or in the form of complex markings or punchings intended for direct handling by automatic sorting and accounting machines.
3. Translating equipment to convert information derived from the trunk into suitable signals for actuating the recorder.
4. Storage and switching circuits to permit the use of a common recorder for a number of trunks.

In contrast, distinguishing features of the system to be described are:

1. The calling station is identified by the subscriber dialing his own number.
2. The recorder consists of a simple punch mechanism perforating a single row of holes in a tape. The punch is actuated directly by dial pulses.
3. No translating equipment.
4. Each trunk has its own recorder. This is permitted by the simplicity of the recorder, and eliminates the cost of storage and connecting circuits required by a common recorder.

When subscriber toll dialing was first contemplated more than 25 years ago the method of requesting the subscriber to identify himself by first dialing his own number was given consideration. It may seem strange at this late date to revert back to that system as it was originally conceived. Nevertheless, abandonment of the original method in favor of automatic calling number identification builds the equipment up to such a point that it is practical for use only in the larger urban areas where the high density of traffic can support the necessary investment. We, therefore, do not feel that it is a retrograde step to propose an operating method of this kind at this time. Contacts with operating companies have substantiated this belief, the decision being based on the fact that with manual operation the customer is verbally asked to identify his telephone number, hence there should be no adverse reaction to asking him to identify himself by dialing a number instead of giving it verbally to an operator.

A means of checking that the subscriber correctly identifies himself is essential if the equipment is to be completely automatic. Such a check is provided by a check link which responds to the number dialed and verifies that the dialing was received from the line indicated. The equipment at present does not check the party on the line, it being thought that if the incorrect party digit has been dialed, the range of inquiry for locating origination of the call has been reduced to the point where little trouble should be encountered. Although it would be entirely possible to verify the party on the line, the cost of special equipment at each subscriber's telephone would tend to defeat the low-cost objec-

Figure 2. Tape recorder with and without cover

Figure 3. Block diagram of automatic ticketing trunk and checking link

tive of the system. The matter has been discussed with several operating companies, who are inclined to agree with this reasoning.

The method of recording information must be of the simplest in order to keep costs within reason. As the trunk receives both calling and called numbers in the form of dial pulses, the direct recording of these pulses with no intervening translating equipment provides a simple, reliable, and ready solution. Each digit can be represented as a line of holes perforated along a narrow tape, with a space between digits, wider spacing between groups of information, and a still wider space between calls. Duration of conversation can be registered by punching a hole once each minute, and date and time of day can be recorded digitally from a "calendar" as will be described later.

As such a recorder is simple and can be manufactured at low cost, a recorder per trunk is the logical arrangement, eliminating the more complicated universal recorder and associated storage and switching circuits.

The recorder is illustrated in Figure 2. It consists basically of a punch magnet to perforate the tape and a step magnet to feed the tape through the recorder. The step magnet operates each time the punch magnet is energized, and also can be operated independently to provide additional spaces between series of perforations.

Operation

The equipment involved in the automatic ticketing system is shown in the block diagram of Figure 3. The tape recorder, timer, and calendar appear only at one end of the trunk, the other end being the same except for omission of these items.

The timer and calendar are common to a group of trunks or entire office. The timer consists of a clock which transmits an impulse once a minute to any trunk that has been answered, thereby recording as perforations the duration of conversation in minutes. The calendar comprises relay counting circuits, or rotary switches, or mechanically geared contacts, which are driven from the clock to register the time of day and date. When a trunk is connected to the calendar, the calendar transmits impulses to the recorder representing the date and time of day as digits.

The trunk termination consists of relay circuits involving relatively few relays above those required for normal trunk operation, the termination at the non-recorder end being simpler than the one at the end with recorder. The circuits are adaptable for any of the common types of trunk signaling, such as loop dial, composite or carrier, and can be applied to any conventional dial switchboard.

To place a call, the subscriber first dials the single-digit trunk code, then dials his own number, then dials the desired number in the distant exchange. Ringing, answering, talking, and release follow exactly as on a local exchange call.

Assuming the call originated from the recording end, the dialing of the trunk code completes a circuit from the subscriber's telephone through a regular exchange link to the trunk. The trunk immediately seizes a check link.

When the subscriber dials his own number, the impulses are registered on the recorder and also are transmitted to the check link, creating a connection through that link back to the calling line.

At this time, the trunk circuit momentarily "flashes" (answers and unanswers) the regular link. The calling line receives answer supervision in the normal manner, which supervision is picked up by the check link and carried back to the trunk. If the flash received by the trunk over this local loop circuit coincides with the one transmitted, the identity of the calling line is verified. If the subscriber has dialed a line number other than his own, the loop back through the check link is not complete and the flash not received, in which case the trunk returns busy signal and blocks further dialing. As soon as the check has been made, the check link is automatically released and is available for other calls.

The check links can consist of regular exchange links modified to transmit supervision back through the link in the necessary manner. In exchanges with sleeve supervision or having a fourth wire available, the modifications are simple and maximum economy is obtained by using regular links for checking. In exchanges with other types of supervision, the modifications might be more difficult and under certain conditions it may be preferable to install special verification links. Figure 3 has a solid line to show the path verifying with a regular link, and a dotted line if a special link has to be used.

When the subscriber dials the called number, assuming that his own number has been checked satisfactorily, the digits are registered on the recorder and are transmitted over the trunk to the distant office, where the connection is completed in the normal manner. When the call is answered, the trunk engages the common timer, which punches a hole on answer and one each minute thereafter, so that the total number of holes represents the total chargeable minutes for the call.

Figure 4. Completed call registered on tape

When either party hangs up, the local exchange link is released so that the local line is immediately available for other calls. The trunk is held, however, until it receives date and time of day from the calendar. If the calendar is busy transmitting information to some other trunk at that time, the trunk is held until the calendar is free. If several trunks are waiting for the calendar, the calendar transmits to all simultaneously.

If the subscriber encounters a busy line or all trunks or all links busy, he receives the usual busy signal and hangs up. In this case, or in case the called number does not answer, the call is registered as incomplete, no elapsed time nor calendar information being punched on the tape for that call.

A call originating at the distant (non-recorder) end of the trunk proceeds in the same manner as described before, except, that in this case the dialing of the subscriber's own number is transmitted over the trunk so that it may be received by the recorder.

Tape Information

Figure 4 illustrates the appearance of a completed call as it appears on the tape. Information shown consists of:

1. Originating end indication.
2. Calling number.
3. Called number.
4. Duration of conversation.
5. Date and time of day.

As one recorder is used for calls in either direction over the trunk, it is necessary to indicate at which exchange the call originated. This is accomplished by punching a hole in the tape when the trunk is seized from the recorder end. If the trunk is seized from the other end, the preliminary hole does not appear.

Recording of the dialed numbers and the elapsed time has been described previously. The calendar information is recorded on a decimal basis, with one or two digits for the date, one or two digits for the hour of day, and one digit for the tenth of hour.

In the final design of trunk and recorder, all efforts have been concentrated in the one direction of simplicity and low cost. However, when it comes to translating the information from the tape into subscriber's bills, a number of methods can be used depending on the volume of material to be handled which in turn determines the revenue available for mechanization of tape reading and billing.

The simplest way would be to count numerically the perforations on the tape and write out a toll ticket from that information. This would be feasible only when the volume of work was extremely small, though it could be facilitated by a simple indicator to show the number of perforations without requiring counting of each hole.

Another method would be to feed the tape through a simple mechanical or photoelectric sensing device, from which would be derived impulses to actuate counters giving a display of numbers on a panel. Information from the panel then could be transcribed on tickets. A further refinement would be to arrange for automatically photographing the display, to gain speedier operation and eliminate errors in transcribing. To go still further, impulses from the sensing device could operate circuits to prepare punch cards, which in turn could be handled by standard business machines on a full automatic sorting and accounting basis.

A large company with a number of exchanges could afford to install the more complicated equipment, for the volume of tapes to be handled would result in a saving from mechanization; whereas the smaller company with perhaps only a couple of ticketing trunks would not find it desirable to use anything beyond manual transcribing of the information. However, the process could be changed or amplified at any time conditions warranted such a change.

We would like to emphasize the fact that we do not offer this equipment as a complete cure for all of the situations involving automatic toll trunks between community dial offices, but we do believe that it has possibilities of considerably relieving this situation and permitting conversion of manual exchanges which at the present time would not be considered for conversion because of the necessity of maintaining operators at these points. While realizing the method of operation departs considerably from previously accepted subscriber toll dialing practices, this has been done in the interest of economy, as this type of service is never a very profitable operation and any additional costs are difficult to justify. We believe that it will find an application where conditions are such that toll charges over certain routes must be maintained for some time in the future, and it is undesirable to continue with an operator office at these locations for this small amount of service.

No Discussion

Electric Equipment for Heavy-Media Separation Process

J. J. BEAN
NONMEMBER AIEE

K. A. BLIND
MEMBER AIEE

BECAUSE of the depletion of the so-called high grade ores, most of the nonferrous metals, such as copper and lead, are produced today from low grade ores of surprising low gross value. Similarly more and more of our so-called "nonmetallic" minerals like fluorspar, magnesite, and glass sand must be treated in some manner for the removal of impurities to bring them to the high standards previously set when virtually pure minerals could be mined, and on which the consuming industries have been built up.

Due to new labor conditions, the coal mining industry, both bituminous and anthracite, is turning more and more to mechanized mining, which because of its very nature results in the production of coal with increasingly larger amounts of ash, since the machine cannot be operated to mine selectively, choosing only the good coal and leaving behind the waste.

This trend toward lower grade mining products has been met by the introduction of milling methods such as froth flotation and cyanidation in the metal mining field, and better washing practices in coal mining.

Among the newest developments in beneficiation of ores and coal are the heavy-media separation processes, which separate the desired mineral from its accompanying waste by the difference in specific gravity between the two components.

The heavy-media separation process was introduced to the metal mining industry in the mill of the American Zinc Lead and Smelting Company at Mascot, Tennessee in 1938, and its use has grown rapidly until now a wide variety of materials including lead-zinc, and zinc ores, iron ore, fluorspar, magnesite, garnet, and tin ore are being commercially beneficiated through its use.

The process is a practical application of the old laboratory technique of heavy liquid separation, wherein a mixture of solids of different specific gravities is immersed in a liquid having a specific gravity intermediate between the high and low gravity components of the mixture. The portion of lower specific gravity than the liquid floats while that of higher specific gravity sinks and thus a separation is made. A very simple example would be the separation of a mixture of sand and sawdust by shoveling it into a bucket of water.

Although heavy liquids having the correct specific gravity to make separations of some materials, notably coal from slate, are available, their use in a commercial plant is difficult if not impossible from both the economic and the handling standpoints for they are expensive, generally toxic, and hard to recover. In plant practice great care would be required to prepare the raw feed to prevent the penetration of the liquids which would make their subsequent recovery difficult, and to provide vaportight systems to prevent losses by vaporization and hazards to health.

The heavy-media separation method utilizes the same general principle, but employs a suspension of a finely ground (90 per cent-200 mesh) heavy solid in water. Such suspensions have some of the properties of a true liquid, one being the ability to float materials of lighter gravity than that of the suspension. Suitably heavy materials for such suspensions are galena, barite, ferrosilicon, and magnetite. These heavy solids when mixed with water provide a cheap, recoverable medium, which is nontoxic, noncorrosive, and may be used in a system open to the atmosphere.

However, since they are suspensions and not liquids, they present some problems from the standpoint of settling rate, viscosity, particularly toward the upper limit possible with a given solid which may be roughly stated as half that of the specific gravity of the solid, and viscosity due to the introduction of fine lighter material from the ore itself.

Originally the problem of removing contaminants from the medium suspension was met by recovering the medium solid from the dirty suspension by means of froth flotation. This method is entirely practical and gives excellent results on certain ores; however, it has some disadvantages which are inherent with any flotation operation. Principal of these is the fact that a froth flotation operation must have steady conditions with respect to feed rate, dilution, reagents, and character of material to be floated. These limitations of the flotation process mean that the heavy-media plant operator must operate with the flotation plant limitations in mind, and is not entirely free to adjust the amount of medium cleaning to the needs of the heavy-media plant. Furthermore, the soft nature of galena, which is the most common nonmagnetic solid used for this type of medium, results in its degradation in use, and the very fine galena resulting is hard to float. It oxidizes readily and becomes increasingly hard to recover by froth flotation.

When the heavy-media separation process was first tried on iron ores, these limitations of froth flotation cleaning were so great that a new medium had to be developed, and the use of a magnetic solid was conceived. Ferrosilicon containing 15 per cent silicon was selected as the most suitable since it was hard, rela-

Paper 50-230, recommended by the AIEE Mining and Metal Industry Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted August 19, 1948; made available for printing August 23, 1950.

J. J. Bean is with the American Cyanamid Company, Stamford, Conn., and K. A. Blind is with the Dings Magnetic Separator Company, Milwaukee, Wis.

Figure 1. American Cyanamid Company heavy-media separation standard flow sheet

tively cheap, and highly magnetic, and of course, magnetic separators could be used to clean it efficiently and cheaply.

Later, when the treatment of coal was started, which requires a lower specific gravity medium, magnetite was selected as the most suitable material. Other materials such as roll scale from a steel mill may be used.

Through the use of ferrosilicon and magnetite, either singly or in combination, a wide range of gravity is possible, the lowest being about 1.25 and the highest about 3.4.

In general, it may be stated that heavy-media separation processes will treat any ore in which the valuable mineral constituents have an appreciable difference in specific gravity from that of the worthless gangue. This difference in specific gravity can be less than that required for efficient separations by jigging or tabling.

In general, three types of ore are amenable to heavy-media separation processes:

1. Ores whose valuable constituents are liberated from unwanted mineral at a grind of 48-mesh or coarser.

2. Ores containing valuable minerals in the form of lenses or veins separated from each other by barren gangue.

3. Ores containing barren gangue which can be rejected after coarse crushing.

The heavy-media separation processes are capable of performing three main functions:

1. The rejection of a waste product leaving an enriched product for further concentration by other methods after reduction in size.

2. The production of a finished concentrate and a rejectable waste in one operation.

3. The production of a finished concentrate and a low grade reject for additional treatment.

Heavy-media separation processes have a wide field of usefulness as preconcentration methods for removing gangue, at low cost, after coarse crushing. They, therefore, offer a cheap and effective means for making ore out of sub-ore, waste dumps, and tailings, by concentrating the valuable constituents into a smaller product of sufficiently high grade to warrant treatment by more expensive methods such as flotation or cyanidation.

The application of heavy-media separation processes is closely related to the type of mining practiced or contemplated. It is, therefore, necessary to study the geological structure of the deposit to determine whether high cost selective mining methods may be eliminated through use of these processes to reject waste rock mined over greater widths. Similarly, by locating the heavy-media plant underground a hoisting bottle neck may be eliminated, at far less expenditure of time and money than would be required to sink and equip a new shaft. Installation underground, moreover, provides a waste product for back filling at no additional cost.

Of particular importance to established operations are the opportunities through heavy-media separation processes for increased profits by lowering of costs, for increases in production, and for reduction in over-all labor requirements per ton of metal or mineral produced. An existing flotation mill, for instance, may greatly increase its metal

Figure 2. Flow sheet heavy-media separation-full-size range treatment

Figure 3. Internal wiring diagram for Crockett separator

output through increasing mill heads by installing heavy-media separation before fine grinding.

In general, it may be stated that heavy-media separation processes are applicable to the separation of sizes down to as small as 35 or 48 mesh. Although in some instances it is feasible to handle run-of-mine ore without presizing, the efficiency of separation drops off on sizes below 48 mesh.

For the treatment of sizes up to $3^1/_4$ inches, a separatory cone may be used. Other apparatus is available for treatment of sizes larger than $3^1/_4$ inches.

Regardless of the type of separatory vessel used, the underlying principles of heavy-media separation processes remain unchanged, although the flow sheet may vary. In this connection, as will be explained later, the treatment of full-size range material, including sizes below 10 mesh, necessitates the use of more equipment than is required for handling sizes down to 10 mesh only.

Highly efficient separations have been made on coal at specific gravities ranging from as low as 1.25, using magnetite medium. With this medium it is possible to make highly effective separations up to 2.20 specific gravity. For the range 2.20 to 2.90, mixtures of magnetite and ferrosilicon are satisfactory. Above 2.85, ferrosilicon alone is used and separations at 3.40 specific gravity have been made commercially.

Magnetite (Fe_3O_4) is a naturally occuring mineral found in abundance in many countries and is mined as an iron ore.

Ferrosilicon (Fe 85 per cent, Si 15 per cent) is a furnace product obtainable from various suppliers in several grades of suitable fineness.

The essential steps in heavy-media separation processes are:

1. Preparation of the feed.
2. Heavy media separation.
3. Removal of medium from the separated products.
4. Reclamation and cleaning of the medium for reuse.

Primary slimes and fines which are not amenable to sink and float separation are objectionable because they dilute the medium and increase its viscosity. Such fines and slimes should be largely removed prior to heavy-media separation.

Fine granular or colloidal particles having a lower specific gravity than that of the solid constituent of the medium have two definite disadvantages:

1. They lower the specific gravity of the medium.
2. They reduce the separating efficiency of the medium because of increased viscosity.

The harmful effect of slime can be reduced to a great extent by the use of efficient methods for cleaning the medium. The development of ferrous media and magnetic recovery has eliminated the need for complete slime removal before treatment because of the efficiency of magnetic concentration. At one operation using ferrosilicon the ore treated is high in slime content. The only equipment employed for 125 tons per hour is one 4 by 12 foot screen fitted with washing sprays for the first six feet only. This treatment only partially deslimes the ore, in fact a substantial quantity of clay balls is sent with the ore to the heavy-media cone. With other types of sink-float processes, the treatment of such slimey ore tends to result in medium contamination and high viscosity, but with ferrous media and magnetic cleaning, the slime is rejected from the medium as rapidly as it is introduced and a satisfactory separating medium is maintained without difficulty.

A clearer understanding of the basic principles of separation, and the method of recovery and cleaning of media can best be obtained by referring to the flow sheet shown in Figure 1. This flow sheet is the one most commonly used for treatment of sizes coarser than 10 mesh, using ferrous media.

For the treatment of sizes finer than 10 mesh, a modified flow sheet is used wherein separate medium cleaning circuits are employed for selectively separating and recovering medium from fine float and fine sink. This innovation is discussed later.

Referring to Figure 1, it will be noted that the finer sizes are removed from the feed by the primary washing screen (1) before it enters the separatory cone (2).

In the separatory cone (2) which is filled with ferrous medium of preselected gravity, the low gravity minerals float on the surface of the medium and are removed by overflowing a weir located opposite the point of entry of feed. The heavier gravity minerals sinking through the medium are continuously removed from the cone by means of an "air-lift" (3). The latter, as will be noted, is, roughly, a J-shaped pipe of suitable size connected to the bottom of the cone. Jets of compressed air introduced at the bottom of the vertical section of this air lift serve to elevate the sink particles in an effective and economical manner.

The float and sink products discharged from the cone go to drainage and washing screens (4) (5). In the particular flow sheet shown in Figure 1, the float and sink products are treated on single drainage and washing screens divided longitudinally by a partition to keep the products separate. In large size plants, separate drainage and washing screens are provided to handle the float and sink products.

The purpose of the drainage screen (4) is, as the name implies, to drain off and remove the medium from the float and sink products. Normally, more than 90 per cent of the medium discharged from the cone with the float and sink products drains off on the screen or screens mentioned, and is returned directly back to the cone without further treatment by means of one or more centrifugal pumps (6).

The float and sink products pass along the drainage screen, or screens (4) to the washing screen, or screens (5), where substantially complete removal of the adhering medium is accomplished by means of water sprays as indicated in Figure 1.

The screen oversize products are discharged as concentrate or tailing.

Positive and simple control of the desired cleanliness and separating efficiency of the medium removed by the drainage screens and circulated directly back to the separatory cone is provided by a readily adjustable diverting chute located underneath the drainage and washing screens (4) (5). By means of this chute, more or less medium may be diverted from the drainage hopper to the washing hopper and thence to the cleaning circuit.

The medium removed by washing is too

Figure 4. External wiring diagram for Crockett separator

dilute and, in many instances, too contaminated with fine impurities to permit of its being returned directly back to the separatory vessel. Accordingly, it is treated in a novel manner: the undersize from the washing screen (5) first flows by gravity or is pumped to a medium reclamation thickener (8). Just before it enters the thickener, the diluted medium passes between a set of magnetizing blocks (7). These latter serve to magnetize the discrete ferrosilicon or magnetite particles whereby they become mutually attracted and flocculate. The net result of this is faster settling of the particles in the thickener with consequent advantage of requiring less thickener area and depth than would otherwise be necessary.

The overflow from the thickener (8) may be used for spray water as shown in Figure 1. Alternatively, the overflow from this unit may be sent to another thickener which may serve as water-storage and clarification means for the entire operation. In the latter event, a portion of the overflow from this secondary thickener would be used for spray water over the previously mentioned washing screen (5).

In addition to serving as a means for dewatering the medium, the thickener (8) also provides storage for medium during off-operating periods. For this reason, this thickener is provided with a motorized device for raising and lowering the rakes. When the plant is shut down, the rakes are lifted to some point above the settled solids. When operations are resumed, the rakes are gradually lowered into the settled solids and the latter are then rendered sufficiently mobile so that they may be eventually removed by means of a centrifugal pump (10) and thereby sent to the cleaning circuit comprising at least two magnetic separators (11) (12).

Figure 5. Outline drawing of Crockett separator

Figure 6. Longitudinal section through magnet bank

When it is desired to increase the specific gravity of the medium in the separatory cone during operation in order to meet some change in characteristics of feed, an extra amount of medium can readily be introduced into the circuit by lowering the rakes in the thickener.

The magnetic cleaning circuit, as shown in Figure 1, comprises a primary (11) and a secondary (12) Crockett-type magnetic separator. These separators are of the belt type, the magnet assembly being mounted just above the lower section of the belt. Feed is added under the belt as shown and the fines not immediately picked up by the action of the magnets and carried by the rubber belt, are dropped and eliminated through the hopper, as shown. This tailing, or reject, goes by gravity to the secondary magnetic separator (12) for additional treatment in order to recover any traces of medium not picked up in the primary separator. The tailing from the secondary separator (12) goes to waste; or if sufficiently valuable, may be sent to some other form of cleaning such as froth flotation.

The medium recovered on the belt of the primary magnetic separator (11) is discharged into the hopper, as shown in Figure 1 after the belt passes the influence of the magnetic field. This recovered medium is too diluted with water to return directly to the separatory cone (2) and it is therefore treated in the following manner.

As shown in Figure 1, the primary magnetic separator concentrate flows by gravity, or it may be pumped, to a densifier (13). The densifier is essentially a screw-type classifier, but acts as a thickener and storage reservoir for clean medium. It is not a classifier in the accepted sense of the term. The machine must be fed at the end by means of a feed box, and overflows at the sides—just the opposite of a classifier. The screw is a double-helix flight and is equipped with a variable-speed drive.

Either a manually operated or motorized-lifting device is provided to raise or lower the screw as required.

The densifier performs the important function of assisting in the regulation of the specific gravity of the medium in the separatory cone in addition to dewatering the medium recovered by the magnetic separators.

The medium removed by the secondary magnetic separator (12) may join the flow of medium recovered by the primary separator (11). Alternatively, as shown in Figure 1, it may join the overflow of the densifier (13) which returns to the thickener (8).

The screw discharge of the densifier returns by gravity to the separatory cone (2) via the drainage hopper and medium return pump (6). Before it reaches the drainage hopper, however, it passes through an a-c demagnetizing coil (14) as shown in Figure 1. This is an essential step in the heavy-media separation flow sheet. The dispersing effect imparted to the particles of medium by the action of the demagnetizing coils gives fluidity to the medium in the separatory cone without which satisfactory operation could not be maintained.

As stated previously, the densifier (13) provides a means for ready adjustment of the specific gravity of the medium in the separatory cone. The medium discharged by the screw is of considerably higher specific gravity than the medium in the cone. Therefore, water may be added to the medium returned to the cone by the pump (6). Ordinarily, any required adjustment of specific gravity of medium in the cone is done most quickly and easily by simply turning a valve to regulate the flow of water.

A bucket elevator, not shown in Figure 1, is used to introduce new medium into the circuit, and also is used as a means of returning any clean-up material from floor washing to the system. When necessary to dump the separatory unit, this elevator is used to return the medium, as well as the intermixed ore, to the circuit. In some plants a pump is used to advantage instead of an elevator.

The results of recent continuous pilot plant testing at Stamford have shown the possibility of extending the application of heavy-media separation to the treatment

Figure 7. Transverse section through magnet

of material as fine as 28 mesh to 48 mesh.

For the treatment of sizes below 10 mesh, a modified flow scheme has been developed. Essentially, this flow scheme involves the use of dual magnetic cleaning circuits wherein the undersize float and the underize sink products from the screens are separately subjected to magnetic separation. The magnetic separators recover the medium for reuse and the tailings from these separations are either a finished float or a finished sink product as the case may be.

The flow sheet shown in Figure 2 describes the equipment used and the flow of products and medium through the circuit.

It will be noted that, just as in the case of the flow sheet shown in Figure 1, a certain portion of the medium removed on the drainage screens is returned directly back to the separatory cone. The amount thus returned is controlled by the position of the diverting chute and is dependent upon the quantity of undersize float and sink in the original feed. It will be apparent that when treating a feed containing a large proportion of undersize material, it becomes necessary to divert a greater amount of drainage medium to the cleaning circuit than would be the case when the cone feed contains a smaller proportion of fines. In other words, the amount of fine material that can be recirculated back to the cone with the medium depends on just how much can be tolerated in the cone without interfering with the separatory efficiency of the medium.

Eventually, of course, all of the fine material in the separatory cone circuit reports as finished float or finished sink. The advantage of recirculating a portion of the fines with the drainage medium is that a saving in the size of magnetic separator units is thereby effected. Instead of having to clean at one time all of the medium and accompanying fines discharged from the cone with the float and sink products, only a portion of it goes to the magnetic separators, the remainder is recirculated back to the cone.

The electric equipment in heavy-media plants generally is similar to that used in mills and coal washers.

The motors should all be splashproof and in certain places, for instance the pump motors, they should be totally enclosed fan-cooled so that the plant can be washed down readily without fear of injuring the motors.

Usually magnetic across the line starters are used so that the various pieces of equipment can be readily interlocked to prevent burying of the units with feed in the case of the failure of one unit. This interlocking is similar to that used in conveying systems.

Since demagnetizing and magnetizing of the medium are vital to the proper operation of the plant, audible signals are provided to indicate unit failure.

The tailing discharge of the final magnetic separators is provided with a magnetic trip which operates when the direct power fails and diverts the contents of the magnetic separator to the thickener or to a sump to prevent its loss.

Electrically the most important devices are the magnetic separators, the demagnetizing coil, and the magnetizing blocks. These are described in detail later in this paper, but it might be well to outline briefly their requirements here.

The magnetic separators must recover virtually 100 per cent of the magnetics going to them in a reasonably clean product. They must handle widely varying loads without loss of efficiency and with a minimum of adjustment or attention.

The demagnetizing coil must be rugged, do a thorough job of demagnetizing the cleaned medium, and have a large capacity.

The magnetizing blocks must be rugged, waterproof, and of such strength that the medium is magnetized even when flowing at a rapid rate. For this purpose, both permanent magnets and electromagnets are used. There are advantages to both types and the final choice is largely one of personal perference.

Figure 8. Outline drawing of demagnetizing coil

Figure 9. Magnetizing blocks field distribution in passage way of feed

Crockett Magnetic Separator

The Dings high intensity Crockett-type submerged belt magnetic separator is designed for wet separation. The separator consists of a stationary curved bank of eight magnets, partly submerged in water under which passes the conveyor belt. The pole shoes are located outside the magnet casing and are in close contact with the traveling belt, being separated from it only by a lubricating film of water.

The magnet is suspended from the main structure of the separator, the belt is supported by a head and tail pulley. The driving power is supplied by a motor with gear reducer or gearhead motor. The feed to the separator must be wet and is fed to the separator on a rubber-lined feed launder at from 5 to 60 per cent solids. The launder feeds the material below the first and second magnetic poles which lift the magnetic particles from the pulp.

The launder is so designed that the material enters the water tank just at the point where the first magnet pole is located, retarding its speed and permitting complete pickup action.

The main conveyor belt continuously in motion transfers the magnetic particles from pole to pole through the water tank. Successive poles are of alternate polarity and severe agitation is the result. This agitation permits the nonmagnetic material to be released and discharged into the tailing section. The magnetic particles continuing their travel are given a final spray under the last three magnet poles and a clean concentrate is deposited at the head of the separator.

It is important that the pulp passing down the feed launder approaches the

water level in the tank at the first pole of the magnet.

The weirs located on either side of the tailings section are a convenient means for adjustment of the water level and provide an overflow channel for the slimes.

The magnet bank consists of two subdivisions, the pickup and concentrate sections which are treated as individual circuits and are connected in parallel. The internal electric connections are shown in Figure 3 and the external connections in Figure 4. Most of the heavy-media installations can tolerate a certain amount of carry-over of nonmagnetic material into the concentrate. The poles of the concentrate section remain fully excited and the water sprays under the concentrate section, Figure 5, are kept inoperative.

For installations where a clean magnetic concentrate is required, a rheostat is inserted in series with the electrical circuit of the concentrate section and the magnetic strength of the last four poles can be varied. The decreased intensity permits particles of smaller size or lower susceptibility to be dropped or discharged into the tailings compartment. The water sprays extend transversely across the belt and can be controlled individually. They consist of pipes with a large number of fine openings or a continuous fine slot through which the water is directed against the burden of the belt. The final adjustment is made during initial operation to obtain a clean magnetic concentrate without loss of ferrosilicon or magnetite in the tailings discharge. The opening in the discharge gate at the lower end of the tailings tank is adjusted to obtain the proper amount of overflow on the weirs located on the lateral sides of the tailings tank.

The arrangement of the magnetic circuit is shown in Figure 6. The housing of the magnet bank is made of nonmagnetic steel and entirely waterproof. The interspace between the pole shoes lying external to the magnet housing are filled with wooden blocks properly fitted and treated for continuous exposure to water.

Figure 7 shows a transverse section through the magnet bank. This separator is entirely automatic and continuous in operation, produces a sharp separation and maximum recovery of the magnetic solids in the pulp. Operating results obtained in actual installation are recorded in Table I.

The Crockett separator requires a small amount of d-c excitation, the power requirements for the drive are very nominal despite the magnetic force between magnet and magnetic particles to which the belt is subjected. The friction between belt and magnet is considerably reduced through the introduction of water between belt and magnet bank. Capacities and operating data are given in Table II.

Although the Crockett separator operates within a small fraction of 100 per cent as shown in Table I, it is advisable to install a secondary Crockett which is fed by the tailings from the first machine as a precautionary measure in case the primary Crockett should become inoperative and large amounts of ferrosilicon would be lost permanently.

The secondary Crockett in addition will recover a small amount of magnetic material which is not recovered by the first separator.

36	41	240	1,700	2	70

Demagnetizing Coil

The purpose of the demagnetizing coil is to disperse the highly magnetized particles of the medium magnetite or ferrosilicon and is placed in the flow sheet following the classifier.

Ferromagnetic substances when exposed to the influence of magnetic fields retain a certain amount of magnetism defined as coercive force and residual flux. Each particle has become a miniature magnet and the implied coercive force must be removed.

Ordinary magnets of small dimensions can be placed between the poles of a rotating magnet and slowly removed from their original position or they can be placed within a solenoid. Gradual reduction of the exciting current decreases the existing magnetism following the characteristic of the Hysteresis curve to zero or near zero.

The demagnetizing coil is a solenoid of 3 to 6 inches in diameter and of 16 to 18 inches in length with a decreasing number of turns from one end to the other briefly called tapered winding. Constant excitation of commercial voltage and frequency is applied to the solenoid and the material passes through the coil in the direction of decreasing taper. A solenoid of this type consists of a tubing and end plates of nonmagnetic material such as stainless steel or bakelite with a coil of the proper number of turns depending on voltage and frequency with a resultant average magnetizing force of 300–400 oersteds. A typical demagnetizing coil is shown in Figure 8.

Magnetizing Blocks

The magnetite or ferrosilicon particles are of extremely fine size and settle very slowly in the thickener. The product coming from the washing screens is therefore magnetized before being fed to thickener.

The rubber hose conveying the material is passed through a magnetic field created by the magnetizing blocks.

The operating principle is shown in Figure 9. A magnetic field originating from two horseshoe-shaped magnets passes

through the rubber hose. Polarity and direction of the two separate halves of the field are shown in the same figure. While the pulp is passing through the rubber hose, the fine particles of magnetite or ferrosilicon are magnetized resulting in flocculation of the solids. The average intensity of the field is approximately 800 oersteds.

Figure 10 shows the actual build up of the magnetizing blocks with waterproof windings and watertight conduit and fittings.

Tractive Force on Particles in a Magnetic Field

A magnet is defined as a body which produces a magnetic field external to itself. The field represents a form of potential energy which is located primarily in the air gap between magnet and keeper. This energy stored in the magnetic field is available to do external work.

The field can be described by subdividing it into a number of channels or flux tubes which are obtained through the method of field mapping. The boundary lines of each flux tube are drawn tentatively and the field area is subdivided transversely to the flux tubes through equipotential lines which intersect the flux lines at right angles. Each small area, which must be approximately a square, then represents the same permeance. A field map typical for the described magnetic separator is shown in Figure 11.

The induction or flux density can be calculated in air from the available magnetomotive force in the winding and the permeance of flux tube in accordance with Maxwell's equations of the magnetic field. Flux density is usually designated by the letter B and measured in lines per square centimeter in the centimeter-gram-second system. The magnetizing force, H, measured in oersteds in the centimeter-gram-second system can be calculated from the magnetomotive force and the dimensional constants of the field.

Figure 10. Outline drawing of magnetizing blocks

The energy in a unit volume or density in a uniform field is represented by the equation

$$\sigma = \frac{H \times B}{8\pi} \text{ ergs/cm}^3 \tag{1}$$

This equation also applies to nonuniform fields where the field is subdivided into a large number of regions of uniform density. For many applications it is sufficient to consider a cross section of the field in order to reduce and solve the problem in two dimensions. Magnetic separation is accomplished in media of the permeability $\mu = 1$ such as air or water and equation 1 can be written as

$$\sigma = \frac{B^2}{8\pi} \text{ ergs/cm}^3 \tag{2}$$

The force available at a certain point of the field is equal to the change of energy which can be stated in this form

$$F = \frac{B^2}{8\pi} \text{ dynes/cm}^3 \tag{3}$$

By substitution the following practical formula can be developed

$$F = \left(\frac{B}{5{,}000}\right)^2 \text{ kg/cm}^3 \tag{4}$$

This formula furnishes acceptable results for the calculation of attractive force in the design of magnets but erroneous results for particles of low susceptibility in a magnetic field.

Feebly magnetic materials do not become magnets themselves and the induction B must be replaced by the intrinsic induction B_1.

Intrinsic induction for a given value of magnetizing force is the excess of the normal induction over the induction in vacuum.

$$B_1 = B - \mu_v H \tag{5}$$

In the centimeter-gram-second system $\mu_v = 1$ therefore

$$B_1 = B - H \tag{6}$$

The relation between intensity of magnetization I, flux density, and magnetizing force is expressed in the formula

$$B = H + 4\pi I \tag{7}$$

or

$$I = \frac{B - H}{4\pi} = \frac{B_1}{4\pi} \tag{8}$$

$$B_1 = 4\pi I \tag{9}$$

Introducing $B_1 = 4\pi I$ in equation 1, we obtain

$$\sigma_1 = \frac{H \times I}{2} \text{ ergs/cm}^3 \tag{10}$$

The intensity of magnetization I depends on the susceptibility k and the magnetizing force H, therefore

$$I = kH \tag{11}$$

and substituted in equation 10

$$\sigma_1 = kH^2/_2 \text{ ergs/cm}^3 \tag{12}$$

The attractive force on the particle is therefore

$$F = \frac{d}{dx}\sigma_1 = kH\frac{dH}{dx} \tag{13}$$

where H is the magnetizing force and dH/dx the gradient of the field at the location of the particle.

The attractive force depends on several other factors besides those expressed in equation 12.

The introduction of the particle in the field distorts the original field. The shape of the particle as well as other forces acting on the particles especially in wet separation must be taken in consideration.

The susceptibility of materials varies with the applied magnetizing force and has different values for various materials. The attractive force to the face of a magnet has been calculated for several minerals and illustrated in Figure 12 based on the formula $F = kH^2/_2$ dynes.

Tractive force for particles exists only in a nonuniform or convergent field. For paramagnetic particles $\mu > 1$ the particle will move in the direction of higher field concentration that is on the separator described it will move towards the edges of the pole. It is evident that if the tractive force on the particle is great enough to attract it to the belt, the holding force is considerably greater and will permit thorough spraying and washing before the particles can be removed forcibly from the belt and dispersed in the surrounding medium.

Figure 11 shows the lines of force and equipotential lines of the magnetic field between two poles. The magnetic system must be designed to provide sufficient magnetic strength at a reasonable dis-

Stability of Voltage Regulators

FRANK E. BOTHWELL
MEMBER AIEE

THE theory of Liapounoff on the stability[1] of dynamical systems under small displacements from equilibrium, together with the Routh-Hurwitz stability criterion, is applied to an n-stage d-c generator employing a 3-terminal nonlinear regulator, such as the vacuum tube or a step resistor, the resistance value of which varies in steps with the control voltage. A graphical method for locating the stability boundary for a general control element with empirically given characteristic is presented. The method is exemplified by a 3-stage generator and a nonlinear vacuum tube as control element. Analytical treatments of the linear control element and of the nonlinear controlled resistance are made, and equations are derived for the stability boundary as a function of the time constants of the generator system and the open loop gain of the complete system. The difference between the stability boundaries of the linear and nonlinear control elements is forcefully expressed by these two examples. It is shown that whereas a raise in the open loop gain produces instability in the circuit employing the linear control element, in the case of the controlled resistance, the opposite effect occurs, and a raise in gain insures stability. A method for the determination of the maximum time constant of a dynamical system subjected to small displacements from equilibrium is derived from a variation of the Routh-Hurwitz criterion, and is applied to the voltage regulation problem.

Inasmuch as the current trend in voltage regulator circuits is toward the use of nonlinear control elements, no sufficient mathematical investigation of the behavior of these circuits has as yet been made. However, as Liapounoff[1] has shown that the stability of nonlinear systems under small displacements from equilibrium is completely determined by the linear perturbation terms, the problem of stability is a linear one, and the location of stability boundaries may be effected by an application of the Nyquist criterion[3] or by means of the powerful methods of Routh[3,4] and Hurwitz.[5]

The fact that stability depends upon linear terms only has led to the misconception that for stability analyses, the behavior of the nonlinear control element is the same as the behavior of the linear one.[6] However, the shift of the operating point of the characteristic of the control element with loop gain and the corresponding change in the slope of the characteristic at the operating point are important in the location of stability boundaries. In fact, in the case of the controlled resistance, a raise in loop gain has an effect on stability just opposite to that for a linear control element.

Analysis of the Network

The generator circuit with its generalized control element is shown schematically in Figure 1. The voltage developed across the control element C is assumed to be a function (with negligible time lag) of its current I_1 and the control voltage V. Denoting this function by $f(I_1, V)$, then

$$E = E_1 + f(I_1, V) \tag{1}$$

Inasmuch as the voltage E_j developed at the jth stage is proportional to its corresponding field current I_{j-1}, a steady-state gain K_j may be defined by the expression

$$E_{j+1} = K_j R_j I_j \tag{2}$$

The Kirchhoff relations

$$E_j = L_j \frac{dI_j}{dt} + R_j I_j \tag{3}$$

together with equations 1 and 2 yield the set of $n+1$ equations

$$\begin{aligned} E &= E_1 + f(E_2/K_1R_1, V) \\ \frac{dE_2}{dt} &= (R_1/L_1)(K_1E_1 - E_2) \\ \frac{dE_3}{dt} &= (R_2/L_2)(K_2E_2 - E_3) \\ &\cdots\cdots\cdots\cdots \\ \frac{dE_n}{dt} &= (R_{n-1}/L_{n-1})(K_{n-1}E_{n-1} - E_n) \\ \frac{dV}{dt} &= (R_n/L_n)(K_0K_nE_n - V) \end{aligned} \tag{4}$$

in the $n+1$ voltages, $E_1, E_2, \ldots, E_n, V$.

The system is in equilibrium when all voltages have reached constant values, that is, when $dE_2/dt = dE_3/dt = \cdots = dV/dt = 0$. These equilibrium values are found by setting all derivatives equal to zero in equation 4. Denoting the equilibrium values of the voltages by subscript 0, one finds

$$\begin{aligned} E_{20} &= K_1E_{10} \\ E_{30} &= K_1K_2E_{10} \\ &\cdots\cdots\cdots\cdots \\ E_{n0} &= K_1K_2\ldots K_{n-1}E_{10} \\ V_0 &= K_0K_1K_2\ldots K_nE_{10} \end{aligned} \tag{5}$$

in which E_{10} is given by the equation (in general nonlinear)

$$E = E_{10} + f(E_{10}/R_1,\ K_2K_1\ldots K_nE_{10}) \tag{6}$$

Small transient motions in the vicinity

Figure 2. Nonlinear control characteristic

Figure 4. Stability boundary for linear control element

of the equilibrium point may be investigated by forming the first variation of equations 4. Setting $E_j=E_{j0}+e_j$ and $V=V_0+v$, one finds the set of linear perturbation equations

$$
\begin{aligned}
&e_1+(f_{I_1}/K_1R_1)e_2+f_Vv=0\\
&\frac{de_2}{dt}+(R_1/L_1)e_2-(K_1R_1/L_2)e_1=0\\
&\cdots\cdots\cdots\cdots\cdots\cdots\\
&\frac{de_n}{dt}+(R_{n-1}/L_{n-1})e_n-(K_{n-1}R_{n-1}/K_{n-1})e_{n-1}=0\\
&\frac{dv}{dt}+(R_n/L_n)v-(K_nK_nR_n/L_n)e_n=0
\end{aligned}
\tag{7}
$$

in which f_{I_1} and f_V denote the partial derivatives of f with respect to I_1 and V, evaluated at the equilibrium point. These two derivatives are of utmost importance in the determination of stability boundaries.

Liapounoff's Theorem

The theorem of Liapounoff states that the stability of a continuous periodic solution of a system of nonlinear differential equations is determined by the linear perturbation equations of the first variation of the system of differential equations. The only cases in which the method fails are those in which either all linear perturbation terms vanish or the system is subjected to large disturbances. Our concern here is the special case in which the periodic solution is the equilibrium point $E_{10}, E_{20}, \ldots, E_{n0}, V_0$.

According to Liapounoff[1] the stability of the original system 4, and hence the stability of the circuit of Figure 1, is governed by the stability of the set of linear equations 7. However the stability of the latter is determined by the location of the roots of the characteristic equation

$$
\left(p+\frac{R_n}{L_n}\right)\left(p+\frac{R_{n-1}}{L_{n-1}}\right)\cdots\left(p+\frac{R_2}{L_2}\right)\times\left[p+\frac{R_1}{L_1}\left(1+\frac{f_{I_1}}{R_1}\right)\right]+K\frac{R_1R_2\ldots R_n}{L_1L_2\ldots L_n}f_V=0 \tag{8}
$$

in which $K=K_0K_1\ldots K_n$. In fact the necessary and sufficient condition that the circuit of Figure 1 be stable is that all roots of the algebraic equation 8 have negative real parts.

Routh-Hurwitz Stability Criterion

Inasmuch as the problem of the stability of the circuit of Figure 1 is reduced to the location of the roots of the polynomial 8, a criterion of stability such as Nyquist's[3] may be employed. However, the Nyquist method is numerical, and at least for this simple network, it is not as profitable as the analytical method of Routh and Hurwitz. This latter criterion is in the form of a relation among the coefficients of the polynomial, and for our purposes, takes the following form: If a_0 and a_n are of like sign, the stability boundary of the equation

$$a_0p^n+a_1p^{n-1}+\ldots+a_n=0 \tag{9}$$

consists of certain branches of the following equation

$$
\begin{vmatrix}
a_1 & a_0 & a_{-1} & -a_{3-n}\\
a_3 & a_2 & a_1 & -a_{5-n}\\
a_5 & a_4 & a_3 & -a_{7-n}\\
\cdots & \cdots & \cdots & \cdots\\
a_{2n-3} & a_{2n-4} & a_{2n-5} & -a_{n-1}
\end{vmatrix}=0 \tag{10}
$$

in which every element with subscript greater that n or less than zero is to be replaced by zero. For example, for second, third, and fourth degree polynomials, the conditions are respectively

$$a_1=0$$

$$\begin{vmatrix} a_1 & a_0\\ a_3 & a_2 \end{vmatrix}=a_1a_2-a_0a_3=0$$

$$\begin{vmatrix} a_1 & a_0 & 0\\ a_3 & a_2 & a_1\\ 0 & a_4 & a_3 \end{vmatrix}=(a_1a_2-a_0a_3)a_3-a_1^2a_4=0$$

Equation 10 will separate the a_0-a_n space into certain finite or infinite regions. To test a given region for stability, it is only necessary to test a single point in the region, for the stability can change only by a crossing of the boundary curve, equation 10. However not all branches of equation 10 are necessarily boundary curves, so that one point in each region must be checked. However this checking can usually be accomplished by inspection.

Returning to the characteristic equation 8 for the voltage regulated generator circuit, one may observe the essential features of stability by consideration of a 3-stage system. In this case

$$a_0=1$$

$$a_1=\frac{R_3}{L_3}+\frac{R_2}{L_2}+\frac{R_1}{L_1}\left(1+\frac{f_{I_1}}{R_1}\right)$$

$$a_2=\frac{R_2R_3}{L_2L_3}+\left(\frac{R_3}{L_3}+\frac{R_2}{L_2}\right)\frac{R_1}{L_1}\left(1+\frac{f_{I_1}}{R_1}\right)$$

$$a_3=\frac{R_2R_3R_1}{L_2L_3L_1}\left(1+\frac{f_{I_1}}{R_1}+Kf_V\right)$$

The coefficient a_0 is greater than zero, and since f_{I_1} and f_V must each be positive for proper regulation, a_3 also is greater than zero. Therefore the stability boundary

Figure 3. Stability boundary for control element characteristic of Figure 2

Figure 5. Idealized control resistance characteristic

is given by the equation

$$\left(\alpha_2+\alpha_3+1+\frac{f_{I1}}{R_1}\right)\left[1+\left(1+\frac{f_{I1}}{R_1}\right)\times\left(\frac{1}{\alpha_2}+\frac{1}{\alpha_3}\right)\right]=1+\frac{f_{I1}}{R_1}+Kf_V \quad (11)$$

in which

$$\alpha_2=\frac{R_2L_1}{L_2R_1},\quad \alpha_3=\frac{R_3L_1}{L_3R_1}$$

Graphical Method

Consider a control element with characteristic as shown in Figure 2. The equilibrium, or operating, point P is determined by the plate battery voltage E, the slope of the load line, R_1, and the gain K of the open loop circuit of Figure 1 defined by the relation

$$K-V_0/E_{10}$$

As the gain is varied, the operating point moves along the load line. One may tabulate the values of the derivatives f_{I_1} and f_V (the instantaneous plate resistance and amplification) as functions of gain K for the given choice of E and R_1. These values, coupled with equation 11 yield the stability boundary shown in Figure 3. The region of stability lies below the surface shown in the form of a contour map.

Figure 6. Stability boundary for a controlled resistance as control element

Linear Control Element

If the characteristic $f(I_1,V)$ of the control element is a linear function of I_1 and V, the derivatives f_{I_1} and f_V are constants, and the stability boundary, equation 11 is, of course, independent of the location of the operating point. Let

$$\alpha_1'=K\frac{f_V}{1+\frac{f_{I1}}{R_1}},\quad \alpha_2'=\frac{R_2}{L_2}\frac{L_1}{R_1+f_{I1}},$$

$$\alpha_3'=\frac{R_3}{L_3}\frac{L_1}{R_1+f_{I1}}$$

and note that $R_1+f_{I_1}$ is the total resistance of the first loop of the circuit of Figure 1, and that α_1' is the gain around the complete closed loop. Equation 11 becomes

$$(1+\alpha_2'+\alpha_3')\left(1+\frac{1}{\alpha_2'}+\frac{1}{\alpha_3'}\right)=1+\alpha_1' \quad (12)$$

and the surface is shown in the form of a contour map in Figure 4. Again the region of stability lies below the surface.

Controlled Resistance

A common control element for high-voltage generators is the controlled resistance. It is a step resistor the resistance value of which varies in steps with the control voltage V. The essential features of its stability in connection with Figure 1 may be observed by assuming that the resistance varies linearly and continuously with control voltage when the latter exceeds a critical value, V_c. Any time lag in the operation of the resistor must either be negligible or must form one of the stages of the generator circuit itself. Thus the control resistance R_c takes the form of Figure 5, or

$$R_c=0 \qquad \text{if } V<V_c$$
$$R_c=K_c(R_1/V_c)(V-V_c) \qquad \text{if } V>V_c$$

The dimensionless constant K_c, the slope of the control resistance, control voltage characteristic when the former is measured in units of R_1 and the latter in units of V_c, plays an important role in the stability of the circuit. In fact, it is readily shown that if $K_c<1$, the system is always stable, regardless of gain, whereas if $K_c>1$, the stability boundary is given by the expression

$$[(1/2)\sqrt{1+\alpha_1''}-1)+\alpha_2''+\alpha_3'']\times\left[1+(1/2)(\sqrt{1+\alpha_1''}-1)\left(\frac{1}{\alpha_2''}+\frac{1}{\alpha_3''}\right)\right]=\sqrt{1+\alpha_1''} \quad (13)$$

where

$$\alpha_1''=4\frac{K_c}{(K_c-1)^2}K_0K_1\ldots K_n\frac{E}{V_c},$$

$$\alpha_2''=\frac{1}{K_c-1}\frac{R_2L_1}{L_2R_1},\quad \alpha_3''=\frac{1}{K_c-1}\frac{R_3L_1}{L_3R_1} \quad (14)$$

Equation 13 may be derived as follows. Using the control resistance characteristic given above, the voltage developed across the control element may be written as

$$f(I_1,V)=0 \qquad \text{if } V<V_c$$

$$f(I_1,V)=K_c\frac{R_1}{V_c}(V-V_c)I_1 \qquad \text{if } V>V_c$$

The operating (equilibrium) values of the various circuit voltages E_{i0} are given by equations 5 and 6. Thus

$$I_{10}=\frac{E_{10}}{R_1}=\frac{2E}{(K_c-1)R_1\alpha_1''}(1\pm\sqrt{1+\alpha_1''})$$

$$V_0=\frac{K_c-1}{2K_c}V_c(1\pm\sqrt{1+\alpha_1''})$$

There are two possible operating points. However in order that the control element have a regulating effect upon the system, it is necessary that $V_0>V_c$. Thus if $K_c<1$, the negative signs must be used, whereas if $K_c>1$, the positive signs are used.

The partial derivatives of the control function $f(I_1,V)$ are now readily found. They are found to satisfy the following relations

$$1+\frac{f_{I1}}{R_1}=-\frac{1}{2}(K_c-1)(1\mp\sqrt{1+\alpha_1''})$$

$$Kf_V=\frac{1}{2}(K_c-1)(1\pm\sqrt{1+\alpha_1''})$$

Using these relations in equation 11, it follows that the stability boundary is given by the equation

Figure 7. Locus of parameter values for which maximum time constant of circuit of Figure 1 with linear control element is $L_1/(R_1+f_{I_1})$

$R_1+f_{I_1}$ is total resistance of first loop in Figure 1

$$[(^1/_2)(\sqrt{1+\alpha_1''}\mp 1)+\alpha_2''+\alpha_3'']\times$$
$$\left[1+(^1/_2)(\sqrt{1+\alpha_1''}\mp 1)\left(\frac{1}{\alpha_2''}+\frac{1}{\alpha_3''}\right)\right]$$
$$=\pm\sqrt{1+\alpha_1''}$$

in which the upper set of signs are used for $K_e>1$ and the lower set for $K_e<1$. It is readily seen that for $K_e<1$ no portion of the stability boundary occurs in the region of positive values of α_1'', α_2'', and α_3'', and the system is always stable. For the case $K_e>1$ the stability boundary takes the form of equation 13.

Thus stability in this case is dependent upon the ratio E/V_c. The surface is shown in contour form in Figure 6. In this case the region of stability lies above the surface. That is to say, the region of instability lies inside the mound enclosed by the surface and the co-ordinate plane $\alpha_1''=0$.

For the stability boundaries of the linear control element and of the nonlinear controlled resistance element, the variable α_1'' is in each case proportional to the circuit loop gain. However the boundaries differ greatly, and in fact the region of stability for the linear control element lies below the boundary, whereas the corresponding region for the controlled resistance lies above the boundary.

Maximum Time Constant

In many applications it is necessary not only to insure stability of the over-all circuit but to insure a degree of stability. That is to say, every root of the characteristic equation must not only have negative real part, but the real part must be larger in absolute value than some given value, b. This, of course, is a way of saying that the maximum time constant of the system for small transients about the equilibrium point must be less than $1/b$. If the substitution

$$p=p'-b$$

is made in equation 9, one may apply the Hurwitz criterion to the resulting polynomial in p', that is, to

$$a_0(p'-b)^n+a_1(p'-b)^{n-1}+\ldots+a_n$$
$$=a_0'p'^n+a_1'p'^{n-1}+\ldots+a_n' \quad (15)$$

and be assured that the stability boundary of equation 15 is the locus of parameter values for which the maximum time constant of equation 9 is just $1/b$. This procedure has been carried out for the linear control element, see Figure 7.

Discussion

Hugh M. Taylor, Jr. (Mississippi State College, State College, Miss.): Dr. Bothwell has written an interesting paper on the generator voltage regulator system. There are some points, however, on which his paper is somewhat confusing. The most important of these is the use of the terms "open loop gain," "loop gain," "gain K of the open loop circuit," "circuit loop gain," and "gain around the complete closed loop." All of these terms except the last are used in variance with the normal nomenclature to mean the gain from the field of generator 1 to the return voltage V without regard to the control element C. Thus, as an example, the statement in the section of the controlled resistance that "For the stability boundaries the variable α_1' is in each case proportional to the circuit loop gain" refers, not to the gain from one point, through the circuit, and back to that point, but only to a portion of this loop.

Equation 12 and the stability boundaries of Figure 4 are more universal than Dr. Bothwell has brought out. Although they are given for the case of the linear control element, no assumptions of linearity were actually made. Thus, these curves apply not only to the circuit containing the linear control element, but to the nonlinear element and the idealized controlled resistance as well.

While working on a thesis project at Northwestern University, I made a study of an electronic-feedback-amplifier analogue of a voltage regulator system with a nonlinear control element similar to that of Dr. Bothwell. This consisted of three stages of voltage amplification with a load resistor in the plate circuit of the last stage. The circuit included three variable capacitors for varying the time constants. The resulting curves are shown in Figure 1 of this discussion with the same terminology as that used by Dr. Bothwell. The experimental curves agree with equation 12, within the accuracy expected.

Frank E. Bothwell: I wish to thank Mr. Taylor for his comments and for the presentation of his experimental results which so well verify the general stability boundary, equation 12.

I should like to point out that equation 11 (or equation 12 if you wish) is merely a partial answer to the question of stability for nonlinear systems, in that it relates the stability boundary to basic parameters in a very implicit manner. Each co-ordinate α_1', α_2', α_3', is a function of the partial derivatives f_{I_1} and f_e evaluated at the equilibrium point. In order to use the boundary in this form, it is necessary for each choice of circuit parameters to calculate the operating point of the system and certain partial derivatives evaluated at the operating point.

In order to avoid this difficulty, equation 13 and Figure 6 were derived for the case of the controlled resistance. They present the stability boundary in terms of the time constant ratios of the generator stages, the gain of each stage, the gain of the feedback path, the applied voltage, the critical control voltage, and the slope of the control resistance curve. Such expressions for stability in terms of circuit parameters have been formalized by the Russians under the name of "Vysnegradskii diagrams".

Figure 1. Experimental and theoretical stability boundaries for an analogue of a voltage regulator system

A Method of Total Design as Applied to Polyphase Induction Motors

C. H. CROUSE
ASSOCIATE AIEE

IN recent years standardization, both within the organizations involved with motor manufacturing and with the various motor manufacturers represented by the National Electrical Manufacturers Association (NEMA) has caused the design and manufacture of various ratings of motors to be restricted to the smallest possible number of stator and rotor punching combinations. Each motor manufacturer, who has been or intends to supply the machine tool industry with motor parts, that is, wound stators and rotors without the shaft bearings, or frame, soon finds the necessity of setting up the various ratings in as few punching combinations as is found necessary to adequately supply the various customer's demands. These punching combinations generally fall not only in the standardized punching diameters as outlined by NEMA but also in the diameters predicated by the demands of the manufacturer's customers.

As an example of the standardization, Table I was taken from the NEMA standard on motors and generators.[1]

To illustrate further, the 8-inch outside diameter series carries 2-pole ratings of $1^1/_2$, 2, 3, 5, $7^1/_2$, and 10 horsepower. Likewise, the other diameters of stator shell include the various standard horsepower ratings between the limits shown in Table I. Obviously, the diameters shown are only a part of the total number of diameters that have been standardized by NEMA or the individual motor manufacturer.

Table I. Two-Pole Motor Parts

Horsepower Rating	Outside Diameter of Stator Shell, Inches
$1^1/_2$ to 10	8
$7^1/_2$ to 20	10
15 to 25	12.375

To anyone faced with the task of providing designs for ratings, which are to be changed over to new or different punching combinations, it is apparent that the amount of calculation necessary would be enormous. The process of standardization often entails considerable amount of calculation in order to observe the over-all picture of the changeover so that intelligent decisions can be made as to what combinations of punchings result in the best performance. The purpose of this paper is to relieve the designer of as much detailed calculation as possible.

It will be shown how the salient points of any particular design can be observed from a set of curves, which are characteristics of any particular stator and rotor punching combination. From these curves the stator winding current density, stator tooth flux density, and full load watts loss can be found for any given core length and horsepower output. These curves can be valuable to the designer in that they allow him to follow the trends of any design as some of the various design characteristics change. The curves allow the designer to choose a design based on some value of current density, stator tooth flux density, or full load watts loss.

In order to illustrate the origin of some of the terms to be used later on, it would be well to show the basis upon which the design process is established. As was illustrated by T. C. Lloyd,[2] the desirable factor upon which to base the design of a motor was the maximum torque. Many motors at the present time are defined, in terms of horsepower, by NEMA solely upon the value of the maximum torque. With an assumed value of maximum torque, the necessary curves for design purposes can then be made.

By the use of the approximate equivalent circuit for a polyphase induction motor the maximum torque equation is:

$$T_m = \frac{7.05}{\text{Syn rpm}} \times \frac{nE^2}{2\,(R_1+\sqrt{R_1^2+X^2})}$$

pound feet

This equation can be modified by use of the ratio R_1/X, into the following form:

$$T_m = \frac{3.53nE^2}{(\text{Syn rpm})\,(X)}\left[\frac{1}{\frac{R_1}{X}+\sqrt{\left(\frac{R_1}{X}\right)^2+1}}\right]$$

If the exact equivalent circuit is used, two additional terms will be introduced. One term is K_r, which is the flux factor made up of K_s and K_p. K_s and K_p are defined as follows:

$$K_s = \frac{X_m}{X_1+X_m}$$

$$K_p = \frac{X_m}{X_1+X_m}, \text{ and } K_r = K_s \times K_p$$

The other term, which can be called τ, is the correction applied to the terminal voltage to take care of the stator impedance drop. This same term appeared as $(OE/ZE)^2$ in a paper by W. J. Branson.[3]

$$\tau = \frac{\text{Tan}\,\frac{\theta}{2}}{1+(1-K_r)\left(\frac{R_1}{X}\right)^2}$$

where

$$\theta = \cot^{-1} K_r \frac{R_1}{X}\left[\frac{1}{1+(1-K_r)\left(\frac{R_1}{X}\right)^2}\right]$$

Paper 50-232, recommended by the AIEE Rotating Machinery Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Oklahoma, October 23–27, 1950. Manuscript submitted October 31, 1949; made available for printing August 22, 1950.

C. H. CROUSE is with Robbins and Myers, Inc., Springfield, Ohio.

The writer wishes to acknowledge the work of Dr. S. S. L. Chang in originating the theory of total design as applied to polyphase induction motors. Dr. Chang's development of the original theory made the present paper possible. The writer also is indebted to T. C. Lloyd for his very helpful suggestions during the preparation of this paper.

Table II. Necessary Design Constants From Which Figures 2 and 3 Were Plotted

7	8.41																			

With the two additional terms, the maximum torque equation becomes:

$$T_m = \frac{E^2 \times 3.53 \times K_r \times \tau \times n}{\text{Syn rpm} \times X}$$

A curve for τ for various values of R_1/X and K_r is shown in Figure 1.

In addition to the equation for maximum torque, three other constants should be derived. These constants are defined as follows:

$$a = \frac{\text{rotor input per phase}}{E^2/X}$$

$$b = \frac{\text{primary current}}{E/X}$$

and

$$c = \frac{\text{secondary current (in primary terms)}}{E/X}$$

With the exact equivalent circuit, a, b, and c are determined from constants available in the equivalent circuit.

$$A_1 = \frac{K_r}{1+(1-K_r)^2(R_1/X)^2}$$

$$B = 1 + A(1-K_r)(R_1/X)^2$$

$$D = R_2/sX$$

$$c = \sqrt{\frac{A_1}{\left(A_1\frac{R_1}{X}+D\right)^2+B^2}}$$

$$a = c^2 D$$

$$b = \frac{c}{\sqrt{K_r}}\sqrt{1+(1-K_r)^2D^2}$$

Since K_r and R_1/X are known for any particular design, A_1 and B can be calculated. Arbitrary values of D must then be assumed for the particular value of slip for which the performance is desired. With A_1, B, and D known a, b, and c can be calculated.

Derivation of Total Design Curves

It has been shown[4] that any stator lamination has a certain inherent volt-ampere rating. The volt-ampere formula can be combined with the maximum torque equation to produce the basis upon which the total design curves can be plotted. The flux per pole in kilolines is:

$$\phi = \frac{E \times 45 \times 10^3}{C \times f \times K_w}$$

$$\frac{E}{C} = \frac{\phi \times f \times K_w}{45 \times 10^3} \qquad (1)$$

If F is the ratio of the total bare conductor area to the total slot area and A is equal to the slot area in square inches

$$I = \frac{A}{C} \times \frac{S_p}{n} \times 12{,}730 \times F \times \frac{1}{D_c}$$

Where D_c is equal to the current density in 100 circular mils per ampere

$$V-A \text{ rating} = nEI = \frac{AS_p\phi f K_w F}{D_c} \times \frac{12{,}730}{45{,}000}$$

$$V-A \text{ rating} = 0.283 F f A S_p K_w \frac{\phi}{D_c} \qquad (2)$$

The maximum torque, as shown before, is

$$T_m = \frac{E^2 \times 3.53 K_r \tau n}{\text{Syn rpm} \times X}$$

Figure 1. τ versus R_1/X for various values of K_r

Nomenclature

$a = \dfrac{\text{rotor input per phase}}{E^2/X}$

A = slot area in square inches

$b = \dfrac{\text{primary current}}{E/X}$

$c = \dfrac{\text{secondary current (in primary terms)}}{E/X}$

C = total series conductors per phase

D_c = current density in 100 circular mils per ampere

E = terminal volts per phase, Y assumed

F = slot space factor, ratio of total bare-conductor area to total slot area

F_L = friction loss per horsepower

$F_w = \dfrac{F_L}{746+F_L}$

FLT = full load torque, pound feet

f = line frequency

I = primary current

K_p = primary leakage coefficient, $K_p = \dfrac{X_m}{X_1+X_m}$

K_s = secondary leakage coefficient, $K_s = \dfrac{X_m}{X_2+X_m}$

$K_r = K_s \times K_p$

K_w = winding factor = distribution factor × pitch coefficient

l_c = one-half average length of conductor, in inches

n = number of phases

$\mathcal{P}_L$ = total leakage permeance

$\mathcal{P}_O$ = open circuit permeance

R_1 = primary resistance, ohms

s = slip = 1 − (rpm/Syn rpm)

S_p = primary slots

W = core width, in inches

X_1 = primary leakage reactance

X_2 = secondary leakage reactance

$X = X_1 + X_2$ = total leakage reactance, where $X_1 = X_2$

X_m = magnetizing reactance, ohms

ae = apparent efficiency = watts input/$3EI$

ϕ = total flux per pole, Maxwells

τ = correction applied to terminal voltage to account for stator impedance drop

$$\theta = \cot^{-1} K_r \frac{R_1}{X}\left[\frac{1}{1+(1-K_r)\left(\frac{R_1}{X}\right)^2}\right]$$

$$T_m = \frac{3.53E^2K_r\tau n}{\text{Syn rpm} \times 2\pi f C^2 \mathcal{P}_L \times 10^{-8}}$$

Eliminating E/C with equation 1 it follows that

$$T_m \times \text{Syn rpm} = \frac{3.53K_r\tau n\phi^2 f^2 K_w^2}{2\pi f\,\mathcal{P}_L(45\times10^8)^2\times10^{-8}} = \frac{0.0277K_r\tau n\phi^2 f K_w^2}{\mathcal{P}_L} \qquad (3)$$

Let $\gamma = T_m/FLT$ and assume slip, $s = 4$ per cent at full load

$$\text{HP} = \frac{\text{Syn rpm} \times T_m}{\gamma}(1-0.04)\frac{1}{7.04\times746}$$

$$\text{HP} = \frac{\text{Syn rpm} \times T_m}{\gamma} \times 1.83\times10^{-4}$$

$$\text{HP} = 5.06\times10^{-6}\left(\frac{K_r\tau n\phi^2 f K_w^2}{\mathcal{P}_L\gamma}\right) \qquad (4)$$

If ae denotes apparent efficiency, equation 2 becomes

$$\text{HP} = \frac{V-A \text{ rating} \times ae}{746}$$

$$\text{HP} = 3.80\times10^{-4}\times FfAS_pK_w(ae)\frac{\phi}{D_c} \qquad (5)$$

Eliminating ϕ between equations 4 and 5, it follows that

$$\text{HP} = 0.0285F^3\left(\frac{AS_p}{D_c}\right)^2\frac{\gamma f}{n}\times\frac{(ae)^2\mathcal{P}_L}{K_r\tau} \qquad (6)$$

When $n = 3$ and $F = 0.27$

$$\text{HP} = 0.000693\left(\frac{AS_p}{D_c}\right)^2\gamma f\frac{(ae)^2\mathcal{P}_L}{K_r\tau} \qquad (6a)$$

With the introduction of $\gamma = T_m/FLT$ the maximum torque equation can be rearranged.

$$\text{Syn rpm} \times T_m = \frac{E^2\times3.53\times K_r\tau\times3}{X}$$

$$\text{Syn rpm} \times FLT = \frac{E^2\times3.53\times K_r\tau\times3}{3.75X}$$

when $\gamma = 3.75$.

If the average friction loss per horsepower is obtained, the following ratio results:

$$F_w = \frac{F_L}{746+F_L}$$

With the preceding equations available, the important relations can then be set down.

$$\text{Rotor input} = \frac{\text{Syn rpm} \times FLT}{7.04}(1+F_w)$$

$$a = \frac{\text{rotor input}}{\dfrac{3E^2}{X}}$$

$$a = (1+F_w)\frac{\text{Syn rpm} \times FLT}{7.04}\times\frac{X}{3E^2}$$

$$a = (1+F_w)\times\frac{\text{Syn rpm} \times FLT \times E^2\times3.53\times K_r\tau\times3}{7.04\times3.75\times\text{Syn rpm} \times FLT\times3E^2}$$

$$a = 0.1338(1+F_w)K_r\tau$$

$$\text{Primary current} = \frac{E}{X}b$$

$$\text{Apparent watts} = \frac{3E^2b}{X}$$

$$\text{Output watts} = \frac{3E^2a}{X}\frac{(1-s)}{(1+F_w)}$$

Figure 2 (left). Total design curves for a 4-pole, 60-cycle, 3-phase induction motor with the ratio $T_m/FLT = 3.0$

Figure 3 (right). Total design curves for a 4-pole 60-cycle 3-phase induction motor with the ratio $T_m/FLT = 3.75$

$$\text{Apparent efficiency} = \frac{(1-s)}{(1+F_w)}\frac{a}{b} \tag{7}$$

Primary copper loss $= Fl_eAS_p$ watts per cubic inches

$$\frac{\text{watts}}{\text{cu. in.}} = \frac{(1{,}273{,}000)^2}{\left(\frac{\text{CM}}{\text{amp}}\right)^2}\times\text{resistivity}$$

$$= \frac{1}{D_e^2}\times 12.73^2\times\frac{1.724\times 1.13}{2.54}$$

$$= \frac{124}{D_e^2}$$

$$\text{Primary copper loss} = Fl_eAS_p\frac{124}{D_e^2} \tag{8}$$

Equation 5 can be rearranged to produce ϕ/W

$$\frac{\phi}{W} = \frac{\text{HP}\times D_e}{3.80\times 10^{-4}FfAS_pK_w(ae)W} \tag{9}$$

Example

From equations 6, 7, 8, and 9, it now is possible to tabulate the various points necessary from which total design curves may be drawn. Table II illustrates the form in which the calculations can be made. The quantities σ_L, σ_O, K_w, R_1/X, and K, have been defined previously and are redefined in the nomenclature.

Figures 1, 2, and 3 show the manner in which design trends can be observed. After the designer has chosen the stator and rotor punching combination as well as the rotor winding, curves similar to those illustrated allow the designer to choose a core width and horsepower combination and observe at a glance the trends which may be expected. Should the full load current density be a prerequisite, then immediately the stator tooth flux density and the full load watts loss can be observed. Likewise, any of the other factors can be established, while the trends of the remaining quantities can be observed. It is hoped that the present process can be of help to designers faced with either changes in existing lines of motors, or the necessity of designing a complete new line of motors.

No Discussion

A Study of Directional Element Connections for Phase Relays

W. K. SONNEMANN
MEMBER AIEE

THE subject of the performance of single-phase directional relay elements for phase fault protection has never been completely analyzed with consideration given to all the possible variables. The analyses which have been made have been limited in scope when intended to be general in nature, or have been slanted toward specific problems. It is the purpose of this paper to extend the boundaries of the generalities of the analysis in the hope that the results will be beneficial to the industry through making answers available which have heretofore been difficult to obtain.

Scope

The relay directional elements to be studied in this paper are single-phase elements only as normally applied for the purpose of making directional discriminations for interphase faults. Polyphase directional relays are excluded on the basis that the method of approach used here is not adaptable to predicting their performance. Ground relays are excluded on the basis that they may be more conveniently studied as a separate problem, free of many of the complications that enter into a consideration of phase relays. The single-phase directional elements that are to be studied are used widely and thus form a conveniently separable bloc in the over-all problem of directional discrimination. This bloc is characterized by certain conditions that may be grouped into the two classifications of (1) fixed, and (2) variable considerations. These are as follows:

Fixed Considerations

There are three relay directional elements for a 3-phase system, one for each phase. There are four types of faults, which are phase-to-phase, single-phase-to-ground, 2-phase-to-ground, and three phase. There are four types of connections which are commonly used, these being the 90-degree, two forms of 60-degree, and the 30-degree connections. (These will be further described.) There is also the consideration of the location of the relays in the power system relative to delta star (or star delta) connected transformer banks, parallel feeds, and zero sequence sources. The author believes that the variables of location in the system can be reduced to three as typified by Figures 1, 2, and 3, and this will be discussed. Multiplying together the numbers involved in the above groups yields a product of 144, indicating that there are 144 facets to the problem to be borne in mind while studying the variable considerations. These are actually reduced to 86 in number, however, by virtue of the facts that: it is only necessary to study one relay out of three for 3-phase faults; some of the relays are not affected by some of the faults; and, the system of Figure 2 is a duplicate of that of Figure 1 insofar as phase-to-phase and 3-phase faults are concerned. These 86 facets are involved in the interpretation of the effects of the variable considerations.

Variable Considerations

The impedances of the power system are conveniently broken down into two single equivalent impedances for each sequence network, which are the impedance of the source up to the relay location, and the impedance of the transmission line from the relay to the point of fault. The impedance of the line may vary from zero representing a close in solid fault, to a relatively large value representing either a fault far removed from the relay location, or else a fault involving an arc of very considerable length. For any given line impedance to the point of fault, the source impedance may be relatively small, large, or in between. The impedance angle of the line may be different from that of the source. The author has considered that the line angle may vary from zero degrees (arcing fault) to 90 degrees lagging, and that the source impedance angle may vary between the limits of 60 to 90 degrees lagging. The zero sequence impedances for the source and line may differ in relative magnitude and impedance angle with respect to each other and quite independently of the positive and negative sequence network impedances. The 86 facets of the problem are interpreted in the light of these variable considerations.

There are other variables which are not covered in this study. These are concerned with the effects of load current and synchronizing current during faults, and the variations possible between the positive and negative sequence networks. This study is limited to the effects of short circuit current only, and is based on the assumption that the positive and negative sequence impedances are identical. In certain special cases, it may be necessary to consider the effect of load current, but it is believed that such cases will be relatively infrequent.

The Four Commonly Used Connections

Directional element connections are conveniently and popularly described in terms of the angle by which unity power factor balanced load current flowing in the tripping direction leads the voltage applied to the relay potential coil with due

Paper 50-233, recommended by the AIEE Relay Committee and approved by the AIEE Technical Program Committee for presentation at the AIEE Fall General Meeting, Oklahoma City, Okla., October 23–27, 1950. Manuscript submitted July 26, 1950; made available for printing August 23, 1950.

consideration given to the polarity of the relay coils. In order that no confusion will exist with regard to what is meant by the terminology used in describing the four commonly used connections, Table IV identifies these connections in terms of the voltage and current used on each relay. In this table, as well as throughout this paper, the double subscript voltage notation used is in accordance with the concept recently recommended to the AIEE Standards Committee for consideration as a recommended standard practice, the sense of which is that when the vector quantity so represented is to be considered as being in the positive half cycle, there is a drop in potential from the terminal of the first subscript to the terminal of the second subscript. Similarly, the single subscript notation used with the currents identify them by phases and in the sense that the vector quantities (currents) so represented are to be considered positive when actually flowing through the line in the tripping direction.

Method of Approach

In the great majority of cases, a sufficient answer is obtained if it is determined whether the torque on the directional element is contact opening or contact closing. This might be termed a qualitative analysis, and is determined purely by the relative phase angle between the current and the voltage applied to the relay and a consideration of the phase-angle characteristics of the relay. In a quantitative analysis, it would be necessary to multiply together the magnitudes of the voltage and current and some function of the phase angle between them as modified by the angle by which the maximum torque line of the relay leads the reference voltage vector, thus determining the magnitude of the torque as well as its direction. The qualitative analysis method serves the purpose, remembering that if the voltage is zero, the directional element will not operate anyway, and this method greatly simplifies the problem. The question then becomes that of determining the relative phase angle between the current and voltage applied to the various relays for the various connections for the various faults. To illustrate the method used, consider relay A operating with the 90-degree connection. It is actuated by the voltage V_{bc} and the current I_a. We may arbitrarily write

$$Z_D = \frac{V_{bc}}{I_a} \tag{1}$$

in which Z_D represents an artificial impedance value obtained by dividing V_{bc} by I_a. Recalling the principles of vector algebra, it is remembered that when the operation is done in polar form, the characteristic angle of the quotient (Z_D) is obtained by subtracting the angle of the denominator (I_a) from the angle of the numerator (V_{bc}). Using the mathematicians' concept for positive angle, it is clear that when this is done, the resulting angle characteristic of Z_D will be that angle by which V_{bc} leads I_a, or, conversely, the angle by which I_a lags V_{bc}. This is exactly the kind of answer that is wanted to determine directional element operation.

It was found through making a general analysis by the method of symmetrical components that the relay voltage and relay current could be reduced to terms involving only the source voltage and the system impedance constants such that when one is divided by the other, the source voltage cancels out and the remaining expression consists of one or more system impedance values together with complex operators. With the expression for Z_D thus being reduced to a function of impedance, it is possible to substitute the appropriate values for the impedances involved for any particular system location and determine the characteristic angle for Z_D for that particular condition, and thereby determine the angle by which the relay current lags the relay voltage. The work of deriving the Z_D formulas for the 86 facets of the problem is given in the Appendixes. All quantities are kept in primary terms, neglecting the instrument transformer ratios.

Tabulation of Results

Tables I, II, and III show the final form of the Z_D formulas. These formulas are applicable to any system which can be reduced to a simplified equivalent represented by Figures 1, 2, or 3, respectively. These three figures are believed to be adequate to represent the portion of interest of any system. While it is possible to make specific applications of the formulas to fit particular conditions, it is desirable to study the formulas in general

Figure 2. System with zero sequence source concentrated at opposite end of transmission line

terms on the basis of determining the maximum possible spread of possibilities. This has been done and the results are shown in Tables V, VI, and VII, corresponding respectively to Tables I, II, and III, and Figures 1, 2, and 3. In Tables V, VI, and VII the relay voltage vector is shown as the reference vector in each case, extending along the x-axis, and the maximum spread of angular position of the current with respect to it, either leading or lagging or both, is shown by the shaded area and with symbolic notation that will be explained.

Systems Studied

Figure 1 represents the simplest system layout wherein the relays at bus G protect the line from G to the fault at F. In general terms, Z_L represents the impedance of the line to the point of fault and includes the arc resistance, if any. The source is represented schematically by the generator having an impedance Z_S. The positive and negative sequence source circuit may or may not include the zero sequence source circuit, so that an alternate location is shown for the latter, illustrating the freedom of variation of sequence source impedances. This figure is adaptable to a section of any system not otherwise bound to be considered in line with Figures 2 or 3. For example, a system section (not shown) feeding the fault from the right-hand side and having similar sequence current distribution factors will not affect the section shown other than through increasing the apparent magnitude of the arc resistance. This contingency is taken care of by the freedom of variation of the line impedance Z_L in the formulas. Again, other ties be-

tween a system section to the right of the fault and the bus G have the effect of changing the value of the source impedance Z_g to use in the formulas as the fault is moved down the line.

There is one effect of a source circuit to the right of the fault which is not adequately represented in Figure 1 and the formulas pertaining thereto, as follows. With a relatively low zero sequence impedance in the grounding source connected to bus G, there tends to be a preponderance of zero sequence current in the line compared to positive and negative sequence currents as faults involving ground are moved closer to the bus G, and to a degree depending upon the magnitude of the positive and negative sequence source impedances to the right of the fault compared with those to the left of the relay. This is illustrated in more detail in Figure 4, fault location 1. With a preponderance of zero sequence current from the left, the effect will be to produce fault current in B and C phases for a phase-A-to-ground fault, and in A phase for a phase-B-to-C-to-ground fault. The formulas in this paper do not take care of this situation. It is dismissed from analysis in this paper in view of the fact that such an analysis does not appear to be strictly necessary for the following reasons:

Figure 4. System showing alternate fault locations

First, it is the prime function of a protective relay to operate when the fault lies in its protected section. Single-phase-to-ground faults are to be cleared by ground relays and they may be eliminated from further consideration because this paper is concerned with directional elements for phase relays. Two-phase-to-ground faults, however, do lie within the domain of phase relays but generally more so when the system is grounded through an impedance. In this illustration the zero sequence impedance connected to bus G is low, no additional impedance being used in the neutral, or else the effect under discussion would exist only to a limited extent. Under these conditions, it may be properly expected that for the more aggravated conditions, even the 2-phase-to-ground fault may or should be properly cleared by the ground relay because of the magnitude of the zero sequence current. With all of this shifting the responsibility to the ground relay, however, it is believed as a result of a separate vector analysis not included here that the preponderance of zero sequence current for a close in fault involving ground would not prevent the correct phase relay directional element from operating.

Secondly, it is a function of protective relays not to trip when the fault is in some other location. If one of the 3-phase relays gives an incorrect directional indication for fault location 1 in Figure 4, it is of no consequence as long as tripping is obtained by another relay. The question then arises if the incorrect

Figure 5. System diagram showing relay location requiring special consideration

indication can cause false tripping if the fault is back of the relay, as in fault location 2. There are two answers to this question. The answer for the relay location as shown in Figure 4 is that the conditions affecting the relays at bus G on line 1 are completely changed by a fault at location 2 on line 2. The preponderance of zero sequence current disappears from all parts of line 1, and the analysis of relay action for this case is made by considering the relays of Figure 2 in reverse.

The second answer is involved when the relay location is as shown in Figure 5, and connected for the tripping direction as shown. In this case, with fault location 1 or 2, and with a heavy preponderance of zero sequence current from the left, it appears quite likely that false tripping might result with three of the commonly used connections, which are the 90 degree, the 60 degree number 2, and the 30 degree. This is because of the tendency of the large zero sequence components to draw the three line currents together in phase position, and since these are used with three different voltages in the three different elements, it appears that at least one is likely to operate incorrectly. If the connection identified as 60 degree number 1 is used, however, the difficulties are removed inasmuch as the relay is then not sensitive to zero sequence components, either current or voltage.
